Introduction

General Characteristics of Cnidarians

The Cnidaria phylum includes sea anemones, *Hydra* (sessile solitary species), corals, sea fans, sea whips (colonial species) and jellyfish (free-swimming species) that live in aquatic (mostly marine) environments (Ruppert *et al.*, 2003). Cnidarians appear to have diverse morphologies, but all members of this phylum universally possess stinging cells called cnidoblasts. Cnidoblasts are unique to the animals of this phylum and are used to define the phylum. The bodies of individuals in the Cnidaria phylum exhibit radial or biradial symmetry, and almost all tissues have a basic structure composed of two cellular layers, the epidermis (outside) and the gastrodermis (inside). A gelatinous-like substance called the mesoglea is present between the two layers of the tissues and maintains the integrity of the tissues and the body. In addition, cnidarian bodies are relatively simple, and well-organized organs or systems that are found in vertebrates are not present in cnidarians, such as vascular and central nervous systems. Cnidarians only have a passive transport system that depends on diffusion; a simple nerve net; some functionally defined tissues such as tentacles for predation, attack and defense mechanisms; and a sac-like gastrovascular cavity used for digestion and absorption.

Body Forms

Cnidarians are present as either polyps or medusae as adults and planulae as larvae. Sea anemones are examples of the polyp forms, while jellyfish are examples of the medusa forms. In the current classification, the Cnidaria phylum is divided into two major groups, Anthozoa and Medusozoa, based on the structure of polyps and the existence of a medusa stage in the life cycles (Fig. 1). Anthozoa is a class that consists of two subclasses, Hexacorallia (stony corals and sea anemones) and Octocorallia (soft corals and red corals). Medusozoa is a subphylum that consists of four classes, Hydrozoa (*Hydra*), Scyphozoa (true jellyfish), Cubozoa (box jellyfish), and Staurozoa (stalked jellyfish) (Technau and Steel, 2011).

Fig. 1 Phylogenetic relationships of the classes in the phylum Cnidaria. The phylum Cnidaria is divided into two major groups, Anthozoa and Medusozoa. Anthozoa is a class that consists of two subclasses, Hexacorallia (stony corals and sea anemones) and Octocorallia (soft corals and red corals). Medusozoans is a subphylum that consists of four classes, Hydrozoa (freshwater *Hydra*), Scyphozoa (true jellyfish), Cubozoa (box jellyfish), and Staurozoa (stalked jellyfish). Modified from Technau, U., Steele, R.E., 2011. Evolutionary crossroads in developmental biology: Cnidaria. Development 138, 1447–1458.

Fig. 2 Schematic representation of cnidarian life cycle. (A) A typical life cycle of anthozoan. (B) A typical life cycle of medusozoan.

Life Cycle

In anthozoans, the typical life cycle begins with the development of fertilized eggs into free-swimming larvae known as planula, which in turn transform into polyps that can undergo asexual reproduction to produce new polyps or form colonies. When the polyps (or colonies) reach certain ages or sizes, they begin to produce gametes for sexual reproduction under suitable environmental conditions (Fig. 2(A)). The medusa stage does not occur in the anthozoan life cycle. Many of the Medusozoa species alternate between the polyp and medusa stages during their life cycles. Similar to anthozoans, the typical life cycle of medusozoans begins with the development of fertilized eggs into planulae, which in turn transform into polyps. However, medusozoan polyps can produce medusae as well as polyps by asexual reproduction. Sexual reproduction generally occurs in the medusa stage (Fig. 2(B)). Considerable variations or modifications in the life cycle can be observed in many medusozoans.

Asexual Reproduction

Many cnidarians have the ability to create genetically identical individuals through asexual reproduction, as summarized in Table 1. Asexual reproduction allows cnidarians to increase the number of individuals in a population and form colonies in a relatively short period. Asexual reproduction mainly occurs in the polyp stage but sometimes occurs in various forms in the medusae and larval (planula) stages.

Table 1 Forms of asexual reproduction in cnidarians

Class	Production of polyps by polyps	Production of polyps by others	Production of medusae by polyps	Production of medusae by medusae	Production of polyps by medusae	Other phenomena related to asexual reproduction
Anthozoa	Budding Fission	Fragmentation Pedal laceration Autotomy Parthenogenesis	–	–	–	Polyp bail-out Polyp expulsion
Hydrozoa	Budding	Budding from stolon Podocysts Frustules Fragmentation Propagules	Budding	Budding Fission	Budding	Reverse development (medusa to polyp)
Scyphozoa	Budding Longitudinal fission	Podocysts Planulocysts Free-swimming propagules	Strobilation (transverse fission)	Unknown	Budding	Planula directly develops into ephyra Reverse development (ephyra to polyp)
Cubozoa	Budding	Regeneration from polyp fragments	Metamorphosis Monodisc strobilation	Unknown	Unknown	Unknown
Staurozoa	Budding	Planula budding Frustules	Metamorphosis (only apical part)	Unknown	Unknown	Unknown

Anthozoa

This class is composed of approximately 5000 marine species that include corals, sea anemones, sea pansies, and sea pens. Anthozoans are exclusively polyp species, and new polyps are principally produced by polyps or formed from a piece of polyp tissue (Table 1) (Harrison and Wallace, 1990; Bocharova and Kozevich, 2011). Budding, which is defined as the development of a new individual from an outgrowth (bud) of an existing parent tissue, may be the major form of asexual reproduction in anthozoans. In solitary species, new polyps are produced by the detachment of buds from the parent polyps. The buds may arise from the base of the parent polyp, body column, or oral disc depending on the species. In some colonial anthozoans possessing a coenosarc (a thin layer of tissue between the polyps in a colony), the buds (new polyps) may arise directly from and remain connected to the coenosarc. The successive budding results in the formation and enlargement of a colony. Fission is another major form of asexual reproduction that commonly occurs, which is defined as the division of an organism into two or more independent daughter organisms. Fission modes are divided into longitudinal fission and transverse fission based on the direction of division. Longitudinal fission is relatively common among anthozoans, but several species (e.g., *Nematostella vectensis*) undergo transverse fission.

Fragmentation is another important form of asexual reproduction that occurs in anthozoans and is defined as the reorganization and development of an entire organism from a fragmented piece of parental polyp tissue. In some sea anemones (e.g., *Exaiptasia pallida*), parts of the pedal disc (the opposite end of the mouth) break off, and each piece develops into a new individual (a phenomenon known as “pedal laceration”). The regeneration of an entire polyp from autotomized tentacles (e.g., the sea anemone *Bolocerooides mcmurrici* and the stony coral *Euphyllia glabrescens*) and tissue fragments (e.g., the soft coral *Dendronephthya hemprichi*) occurs in several anthozoans (Toh and Ng, 2016). The term “fragmentation” is also often used to describe the formation of a large colony from a fragmented piece of a coral colony.

A phenomenon known as “polyp bail-out” is also related to asexual reproduction (Kramarsky-Winter et al., 1997). In some colonial stony corals (e.g., *Pocillopora damicornis*), the polyps leave their skeleton when the corals become unhealthy under unfavorable environmental conditions. The polyp undergoes resettlement and calcification after reaching an appropriate location and forms a new colony by successive asexual reproduction (e.g., budding). A similar phenomenon called “polyp expulsion” occurs in the stony coral *Oculina patagonica*. The polyps leave their colony together with a part of the skeleton. Interestingly, this phenomenon occurs even in physiologically healthy corals in normal environmental conditions (Kramarsky-Winter et al., 1997). In addition, the production of offspring from unfertilized eggs, or parthenogenesis, has also been demonstrated in some anthozoans (Shikina and Chang, 2016).

Hydrozoa

This class is composed of approximately 3000 species and includes some freshwater species. Hydrozoans are generally thought to have a life cycle that alternates between the polyp and medusa stages, but modification of the life cycle occurs in many species in which the polyp or medusa stage is reduced or completely suppressed.

Asexual reproduction occurs in both the polyp and medusa stages with various patterns (Table 1) (Boero et al., 2002). Polyp budding is mainly responsible for the asexual production of new polyps and the growth of the colony. In solitary species (e.g., *Hydra magnipapillata*), buds (new polyps) may arise from the lateral part of the polyp. In some colonial species (e.g., *Hydractinia echinata*), buds may arise from the stolon, which is a creeping, root-like component of the colony that adheres to the substratum. In other species that form erect colonies of polyps (e.g., *Obelia* sp.), the buds may arise from the stolon and the stems of the polyps. In some hydrozoans, polyp budding can also produce podocysts (cellular aggregates containing the cellular and organic compounds required for the formation of new polyp) or frustules (small, simple pieces of tissue with planula-like structures) that can transform into polyps under favorable environmental conditions. In addition, the reformation of a colony from fragmented pieces of polyps (fragmentation) and the formation of propagules in the polyps also commonly occur in hydrozoans.

Hydrozoan polyps generally undergo budding to produce medusae. The buds (or gonophore buds) may develop into new medusae on the polyps and are released to begin the free-swimming medusa stage. However, in many hydrozoans, the medusa stage is no longer free-swimming. The medusae develop incompletely and remain attached to the polyp (Boero et al., 2002). The degree of medusa development (or reduction) on the polyp varies within hydrozoans. Medusae of some species have radial canals, subumbrellar cavities, and velum but do not have tentacles or mouths. Medusae of other species have no traces of medusae-like characteristics except for gonads.

Asexual reproduction of medusae also occurs in hydrozoans (Boero et al., 2002). In some hydrozoans, a single medusa can also directly produce many medusae by fission (e.g., *Cladonema* sp.) or budding (e.g., *Euphyssilla pyramidata*). Budding occurs at specific sites of medusae, including the bell margin, the marginal bulbs, the radial canals, and the gonads, and the budding sites may differ among species. In addition, some hydrozoans (e.g., *Zanclea* sp.) produce polyps directly on the body of the medusae by budding. The buds (new polyps) may arise either on the manubrium or on the radial canals where gonads normally develop. Some hydrozoans (e.g., *Hydra*) have a remarkable ability to regenerate. An entire animal can be regenerated from a small fragment of polyp tissues. *Turritopsis nutricula* is unique as it undergoes reverse development from an adult medusa to a polyp under unfavorable environmental conditions.

Scyphozoa

This class is composed of approximately 200 marine species. Scyphozoans generally have a life cycle that alternates between benthic polyp (known as scyphistoma) and planktonic medusa stages. Modification of the life cycle also occurs in some species.

Longitudinal fission and polyp budding are the main forms of asexual reproduction in scyphozoans (Table 1) (Arai, 1997; He *et al.*, 2015). The buds may arise either from the column of the polyp wall or a stolon, and become small polyps.

The polyps undergo transverse fission to form young medusae after they grow to a certain size under favorable environmental conditions (e.g., temperature, light, and chemical composition of water) at the appropriate time of year. This process, known as strobilation, is not only a mode of asexual reproduction but also a form of metamorphosis. The first sign of the strobilation is the appearance of transverse constrictions at the distal end of the polyp. As the number of constrictions on the polyp gradually increases, the disc-like medusae with eight tentacles become distinct, and the tentacles of the polyp regress. A polyp undergoing strobilation is called a strobila. Within a few days, the young medusae begin to actively contract on the distal part of the strobila and are released from the strobila by transverse fission. The young, free-swimming medusae are now called ephyrae. The number of ephyrae produced by strobilation varies among species and may be influenced by the environmental conditions. The number of ephyrae ranges from one (monodisc strobilation) to many (polydisc strobilation). Strobilation can be experimentally induced in some species (e.g., *Aurelia*) using treatments of iodine-containing compounds.

As another important means of asexual reproduction, some scyphozoan polyps (e.g., *Cyanea* spp.) can produce chitin-covered cysts (also called podocysts) that can directly develop into new polyps. Its formation can be induced under unfavorable environmental conditions (starvation, high temperature, etc.) and the podocysts can survive for several years. The podocysts hatch (excyst) under environmental conditions favorable for the survival of the polyp. The formation of podocysts is thought to be a way to maintain the population. The planulae of some scyphozoans can also produce cysts (called planulocysts) that are functionally similar to podocysts prior to the formation of polyps. In addition, some scyphozoan polyps can produce free-swimming propagules that can also develop into new polyps.

As a form of asexual reproduction of medusae, direct formation of polyps on living medusae has been observed in a species of *Aurelia* (He *et al.*, 2015). In addition, the direct development of ephyra from planula (without polyp formation and strobilation) occurs in some scyphozoans and represents an example of the modification of a typical life cycle. The formation of polyps from ephyrae (or “reverse development”) also occurs in some species (e.g., *Chrysaora hysoscella*, *Rhizostoma pulmo*, and *Aurelia aurita*) (He *et al.*, 2015).

Cubozoa

This class is composed of approximately 50 species. Cubozoans have a typical life cycle that alternates between the polyp (asexual) and medusa (sexual) stages. In asexual reproduction, polyps generally form buds to produce new small polyps (Table 1) (Toshino *et al.*, 2015). For medusa production, an entire polyp directly metamorphoses into a single medusa. However, in some species (e.g., *Morbakka virulenta* and *Carukia barnesi*), only the apical part of a single polyp is transformed into a single medusa and is detached from the polyp (called monodisc strobilation). In the species that undergo monodisc strobilation, the polyp left behind after the medusa detaches can also asexually reproduce by budding. The regeneration of a new polyp from a small portion of the polyp fragment (named residuum) left behind after the medusa detaches occurs in some species (e.g., *Carybdea marsupialis*).

Staurozoa

This class is composed of approximately 50 species. Staurozoans also have a life cycle with polyp (asexual) and medusa (sexual) stages similar to other medusozoans. However, the morphological differences between these two stages are much smaller than that observed in other medusozoan classes. A single medusa is produced by the metamorphosis of a polyp, but metamorphosis mainly occurs in the apical regions of the polyp, such as the formation of arms, gastric filaments, gonads, and adradial tentacular clusters (Miranda *et al.*, 2017). Because the polyp remains attached to the substrate even after metamorphosis into a medusa, staurozoans consequently have a mosaic body structure, in which the apical region has a medusa-like structure, whereas the basal region has a sessile polyp-like stalk during the medusa stage. Strobilation or budding does not occur when the polyps metamorphose into medusae.

In asexual reproduction, budding occurs in both the polyp and early larval stages (Table 1) (Miranda *et al.*, 2017). In the polyp stage, polyps form buds at the lateral region of the calyx (upper part of the polyp) or at the distal parts of some special tentacles of the polyp. The buds break off and are assumed to form frustules that develop into polyps under suitable conditions. In the early larval stages of some species (e.g., *Halicystus octoradiatus*), planulae that have attached to the substrate (microhydrula stage, hemispherically shaped planula) can also asexually produce protuberances (buds) that may become polyps.

Sexual Reproduction

As in other animals, cnidarians also have the ability to create sperm and eggs that contain all the materials required for the initiation of embryonic development and the maintenance of its physiological functions. Sexual reproduction allows cnidarians to not only foster genetic diversity but also facilitate species expansion into different habitats and create new populations. In the following section, the general aspects of cnidarian reproduction are outlined.

Sexuality

Gonochorism (sperm and egg production in separate individuals) is common in cnidarians. In many cases, there is no difference between the appearance of males and females. The type of gametes (sperm or eggs) created in the individual defines the sexuality. Hermaphroditism (simultaneously produce eggs and sperm in an individual) also occurs in cnidarians. For example, approximately 70% of stony corals (order Scleractinia) are hermaphroditic (Harrison and Wallace, 1990). In some anthozoans and hydrozoans, sex changes (or sex reversal) have been observed at different life stages (e.g., solitary mushroom stony corals and *Hydra*). Very little information is available regarding the mechanisms of sex determination in cnidarians. In *Hydra*, the sex of an individual is determined by the sex of the germline stem cells present in the body (Nishimiya-Fujisawa and Kobayashi, 2012).

Gonads

Cnidarians have specific sites for gamete production in their bodies. The sites are generally referred to as gonads (testis or ovary), although cnidarians are regarded to have no true organs. Gonads are very small, thin, and almost invisible when gametogenesis is not occurring, but they grow in size and can be observed to have distinct swelling (or evagination) during active gametogenesis. In many cnidarians, the appearance of mature ovaries and testes differs in size, shape, and color. The gonads of cnidarians generally develop in the gastrodermis, except in some hydrozoans in which the gonads develop in the epidermis of the polyps. The location of the gonads in the body varies between the classes.

Origin of the Gametes

The gametes of some hydrozoans, such as *Hydra* (e.g., *H. magnipapillata*) and colonial hydroids (e.g., *H. echinata*), originate from the interstitial cells (i-cells) that exist in the interstitial space of the polyp column epidermis (Nishimiya-Fujisawa and Kobayashi, 2012). In *Hydra*, the i-cell population primarily contains two types of stem cells, multipotent stem cells (MPSCs) and germline stem cells (GSCs). The MPSCs have the ability to both self-renew and differentiate into multiple somatic cell types (e.g., neurons, gland cells, and cnidocytes) and gametes. In contrast, the GSCs can self-renew but can only differentiate into gametes. Thus, *Hydra* gametes originate from these two types of stem cells. The origins of the gametes in other cnidarian classes have not been well demonstrated. However, cnidarian germ cells are assumed to originate in the endoderm and develop in the gastrodermis where many cnidarians have gonads. In some cnidarians, such as stony corals (order Scleractinia) and some scyphozoans, gametes are classically assumed to originate from i-cells as occurs in hydrozoans. Further studies are needed to demonstrate whether i-cells or cells functionally similar to i-cells also exist in other cnidarian classes.

Spermatogenesis

The detailed processes of spermatogenesis have been well documented in anthozoans, scyphozoans, and some hydrozoans using histological and ultrastructural analyses, and they appear to be similar to that of many other animals. The first recognizable constituent of spermatogenesis is the proliferation of spermatogonia (or interstitial cells) and the formation of spermatogonial clusters. In anthozoans and scyphozoans, the spermatogonial clusters have been observed to move into the mesoglea and form spermatogenic compartments in the mesoglea of gonads, which are called spermaries, cysts, or spermatic follicles (Arai, 1997; Shikina and Chang, 2016). Further spermatogenic processes, such as the successive proliferation of spermatogonia, meiotic differentiation, and spermiogenesis, occur within each of the spermatogenic compartments. During active spermatogenesis, the male germ cells at different developmental stages can be observed simultaneously in a single spermatogenic compartment. In some scyphozoans, male germ cells maintain contact with some testicular somatic cells, which may support the development of male germ cells.

Oogenesis

The processes of oogenesis are well documented in anthozoans, scyphozoans, and some hydrozoans. In anthozoans and scyphozoans, the first recognizable constituent of oogenesis is the proliferation of oogonia or the appearance of early oocytes in the gonads (Arai, 1997; Shikina and Chang, 2016). After oogonia differentiate into oocytes by entering meiosis, the early oocytes move into the mesoglea and develop there until maturation. Oocyte development is supported by specialized ovarian somatic cells (e.g., “trophocytes” observed in scyphozoans) that are in contact with or are adjacent to the oocytes. The somatic cells nourish the oocytes by providing nutritive materials such as yolk proteins. In some anthozoans (e.g., the stony coral *Euphyllia ancora*), several types of yolk proteins such as vitellogenin and egg proteins are produced by ovarian somatic cells and are then transported to and accumulate in the oocytes (Shikina and Chang, 2016). In contrast, the pattern of oocyte development is different in some hydrozoans from that described above. For example, in *Hydra*, oogenesis begins with the proliferation and migration of i-cells to form an ovary (egg patch) on the epidermis of the polyp column. Several thousand i-cells are observed in an egg patch, but only one of the i-cells grows as an oocyte, and the remaining i-cells differentiate into nurse cells. For oocyte growth, nurse cells transfer their cytoplasm to the developing oocytes, undergo apoptosis, and are finally phagocytosed by the oocyte. Hence, in *Hydra*, oocyte development is primarily supported by the fusion of germ-cell-derived nurse cells with oocytes but not by the ovarian somatic cells.

Fig. 3 Spawning of the stony coral *Euphyllia ancora* (Class Anthozoa, Order Scleractinia).

The processes of oocyte maturation are well documented in some hydrozoans. Germinal vesicle breakdown (GVB) and polar body formation occur in the oocytes prior to spawning. In cnidarians, the size of fully grown oocytes may range from 30 μm (e.g., the staurozoan *Halichystus octoradiatus*) to approximately 800 μm (e.g., the anthozoan *Acroporidae*) in diameter.

Spawning and Fertilization

In most cnidarians in which the gonads develop in the gastrodermis (such as anthozoans, scyphozoans, cubozoans, and staurozoans), mature gametes are released into the gastrovascular cavity and expelled through the mouth. In contrast, in some hydrozoans in which gonads develop in the epidermis, gametes are directly released to the surrounding water. External fertilization is typical in cnidarians, but internal fertilization also occurs in some cnidarians that brood their embryos. One of the best-known phenomena in cnidarian reproduction is stony coral spawning events (order Scleractinia) (Harrison and Wallace, 1990). Synchronized spawning of many stony corals (ranging from 10 to more than 100) over short periods (approximately 1 week) has been recorded in various locations in the Indo-Pacific and the Atlantic Ocean (Fig. 3). The presence of species-specific agents that attract sperm to spawned eggs has been suggested in some corals, but cross-fertilization appears to occur occasionally between closely related species. The timing of spawning at each location is becoming predictable with regard to the period (month) of the year, lunar day, and time of day based on previous spawning records.

Factors Affecting Gametogenesis and Spawning

Various environmental and intrinsic factors influence the timings of gametogenesis and spawning, and these factors may interact with each other. The environmental factors include light/dark period, light intensity, moonbeams, changes in seawater temperature, and food availability. For instance, in many cnidarians that spawn annually, the progress of gametogenesis is influenced by seasonal changes in sea surface temperature. The same species that inhabit different geographic regions may respond to different environmental factors, and this may be associated with the surrounding environmental conditions. In contrast, the intrinsic factors include age, body or colony sizes, and nutritional status. In addition, endocrine-like substances such as neuropeptides (LWamide family) and neurotransmitters (serotonin and dopamine) are also associated with the regulation of spawning in some cnidarians (Shikina and Chang, 2016). Little is known about the endocrine regulation of gametogenesis in cnidarians.

Embryonic and Larval Development

In a typical cnidarian life cycle, a fertilized egg develops into a planula, which in turn metamorphoses into a polyp. In embryonic development, the first cleavage is a meridional division that begins at the animal pole. Generally, as the first division is incomplete and the vegetal pole cytoplasm remains partially connected, a heart-shaped figure is formed. The zygote undergoes holoblastic cleavage to form a blastula. Later, gastrulation occurs at the animal pole to form the ectoderm and endoderm, which eventually become the epidermis and gastrodermis, respectively. The site of gastrulation (blastopore) becomes the mouth, and further embryonic development leads to a planula. Planula larvae are generally ciliated and swim with the aboral end (the opposite end of the mouth) in front. The planulae of staurozoans are not ciliated but can move by a series of extensions and reactions (creeping) (Miranda *et al.*, 2017). After locating an appropriate site to settle, the planula attaches its aboral end to the bottom and metamorphoses into a juvenile. In some anthozoans and hydrozoans, neuropeptides of the LWamide family are involved in the metamorphosis (Takahashi and Hatta, 2011). In addition, in some stony corals, metamorphosis requires extrinsic stimuli such as agents produced by bacteria that live in the ocean.

Reproduction in the Platyhelminthes (Flatworms)

Graham Clive Kearn, University of East Anglia, Norwich, United Kingdom

© 2018 Elsevier Inc. All rights reserved.

Background

Platyhelminths (flatworms) have unsegmented, bilaterally symmetrical, soft bodies, with a triploblastic construction (comprising three layers of cells) and lacking a coelom (body cavity), skeleton and anus. The relatively large flatworms (e.g. planarians, tape-worms) are indeed dorsoventrally flattened but many of the small free-living platyhelminths are cylindrical.

Representatives of the main groups of the Phylum Platyhelminthes are illustrated in Fig. 1. Three of these groups, the Monogenea, Cestoda (tapeworms) and Digenea (flukes) are exclusively parasitic. Monogeneans have a single-host life cycle and are mostly external parasites (ectoparasites) on the skin and gills of fishes. Cestodes and digeneans are endoparasites (internal parasites) and have more complex life-cycles, each with two or three hosts, one of which is a vertebrate. Digeneans have an additional endo-parasitic stage in a mollusc.

Traditionally, all the flatworms that do not belong in the three parasitic groups are placed in the Turbellaria. This is not a valid taxon, but is widely used as a convenient term to accommodate largely free-living members such as acoels, rhabdocoels, triclads and polyclads.

Fig. 1 The platyhelminth panorama. (A), an acoel, *Anaperus* sp.; (B), a rhabdocoel, *Paravortex* sp.; (C), a triclad, *Dendrocoelum lacteum*; (D), a polyclad, *Notoplana* sp.; (E), a monogenean, *Entobdella soleae*; (F), a cestode (tapeworm), *Taenia* sp.; (G), a digenean, *Fasciola hepatica*. Acoels lack a digestive cavity – the mouth opens into a syncytium (a mass of nucleated digestive cells). Cestodes lack a gut. h – haptor (attachment organ); i – intestine; m – mouth. Redrawn from Kearn, G.C., 1998. Parasitism and the Platyhelminths. London: Chapman & Hall.

Sexual Reproduction

In the cnidarians (anemones; jellyfish) the reproductive organs consist of nothing more than the gonads themselves, but in platyhelminths the reproductive organs have become remarkably complex. Fertilisation is internal in flatworms and a few have separate sexes (gonochorism), as, for example, turbellarians of the genus *Kronborgia* and schistosome digeneans (Kearn, 1998). However, most platyhelminths are hermaphrodite (male and female gonads occur in the same individual). They are also protandrous, i.e. the male system reaches maturity before the female system, with the exception of gyrodactylid monogeneans which are protogynous (female system is the first to reach maturity). The obvious advantage of the hermaphrodite condition compared with unisexual animals is that whenever two individuals meet bilateral cross-insemination is possible. There is potential too for unilateral insemination and self-insemination.

The Female Reproductive System

The Egg and the Eggshell

Platyhelminth embryos are protected in the outside world by a strong case, usually referred to as an eggshell when the case contains a single embryo, and a capsule when more than one embryo is enclosed, as in some planarians.

In the platyhelminths there has been an important shift in the source of provisions required for growth and development of the embryo or embryos, and for the assembly of the eggshell or capsule. In the primitive flatworms, so-called 'archoophorans', which include the acoel and polyclad turbellarians, the food (yolk) required by the growing embryo is included in the cytoplasm of the egg cell (endolecithal condition) and the shell material is partly derived from a shell gland and partly from droplets located near the surface of the egg cell. In the more advanced flatworms, the 'neophorans', which include most of the platyhelminths that are associated with other animals (symbiosis), an ectolecithal condition has arisen by subdivision of the ovary.

The production of egg cells destined to develop into new individuals is restricted to the compact region of the ovary known as the germarium (Fig. 2). However, the egg cells in the germarium no longer provide significant quantities of yolk. This is now provided by the other subdivision of the ovary called the vitellarium. This is a follicular organ spreading throughout the body of the animal and producing vitelline cells, which make no genetic contribution but contain abundant yolk. The vitelline cells also have the important role as the source material destined to become the eggshell or the wall of the capsule. The shell gland has become redundant.

The ducts from the vitelline follicles coalesce to form a vitelline duct, which joins the oviduct to form the ovovitelline duct (Fig. 2). The vitelline duct may expand to form a vitelline reservoir providing storage for vitelline cells until required. If there is a gut present (tapeworms have no gut), the vitelline follicles are closely associated with the intestine and its branches. This is a significant relationship since flatworms have no blood system and the proximity of gut and vitellarium ensures a supply of nutrients to the actively metabolising vitellarium with minimal transport costs.

Fig. 2 The egg assembly apparatus of the monogenean *Entobdella soleae* in ventral view. do – distal tetrahedral chamber of oötype; du – ducts of oötype glands (Mehlis' gland?); ex – exit of common vitelline duct from the vitelline reservoir; fc – fertilisation chamber; g – germarium; oc – oöcyte; od – ovovitelline duct; ov – oviduct; pr – proximal tubular region of oötype (where the egg stalk is assembled); u – proximal region of uterus (distal region not shown); va – vagina; vd – transverse vitelline collecting duct; vo – vaginal opening; vr – vitelline reservoir; sr – seminal receptacle. Reproduced with permission from Kearn, G.C., 1985. Observations on egg production in the monogenean *Entobdella soleae*. International Journal for Parasitology 15, 187–194. Elsevier, © 1985.

The Oötype and Egg Assembly

Distally, the ovo-vitelline duct expands to form a muscular organ in which shelled eggs or capsules are assembled one at a time (Fig. 2; Kearn, 1998). In the umagillid turbellarians this organ is termed the “primary uterus”, followed in many umagillids by a “secondary uterus” (Shinn (1986) and references therein). However, in spite of using the same term “uterus” these two organs are functionally very different, the first being the site of egg/capsule assembly and the second acting as a store for shelled eggs or capsules (see below). Consequently, the terms “oötype” and “uterus” are preferred here (Fig. 2; Kearn, 1998), in place of “primary uterus” and “secondary uterus” respectively, as, for example, in Shinn (1986).

In the monogenean *Entobdella soleae* mature egg cells (oöcytes) are fertilised in a germarial fertilisation chamber (Fig. 2). One of these fertilised oöcytes is released and makes its way along the ovovitelline duct to the oötype, followed by a stream of vitelline cells from the vitelline reservoir. Vigorous contractions of the oötype are accompanied by release of vitelline droplets from the vitelline cells. These droplets coalesce around the contents of the oötype to form the eggshell. The oötype acts as a mould and presses the shelled egg into shape – a tetrahedron in *E. soleae*.

Quinone-Tanning

The eggshell/capsule wall is water-white when first made but undergoes a gradual change in colour from water-white to golden brown (Kearn, 1998). This colour change is the visual manifestation of a chemical reaction that leads to changes in the properties of the shell/capsule wall material from soft and pliable to hard and tough. Resistance develops to physical and chemical damage and, in particular, to attack by proteolytic enzymes (i.e. enzymes that digest proteins). These changes are attributable to the process of quinone-tanning or sclerotisation (see review by Waite (1990)). The chemistry of this process is not fully understood but basically it is as follows: catechols are oxidised by the enzyme catechol oxidase to quinone, which then combines with protein.

If the presence of catechols, catechol oxidase and protein indicate the presence of the quinone-tanning process, then the reaction is widespread throughout the Animal Kingdom. It occurs in the walls of spores, cysts, egg capsules and cocoons in protozoans, platyhelminths, nematodes, molluscs, annelids, arthropods and elasmobranch fishes and is prevalent in other structures such as cnidarian skeletons, byssus threads and shells of molluscs and arthropod cuticles.

Catechols, catechol oxidase and proteins are present together in peripheral droplets in the vitelline cells or in the cortical granules of archoophoran egg cells. Why these components do not interact prematurely is not known. Whatever the mechanism of quinone-tanning is, it renders eggshells/capsules physically strong and chemically resistant. Tanned shells/capsules provide sealed compartments to hold vitelline cells and egg cells in close proximity, preventing foreign microorganisms from gaining access to resources destined for the platyhelminth embryos. In fact, Macdonald (quoted by Kearn (1975)) demonstrated that shelled eggs of *Entobdella soleae*, fed experimentally to various crustacean predators, pass through the gut of the predator intact, and, provided that the eggshells are not punctured, are capable of continuing to develop and hatch. This provides experimental support for the suggestion of Llewellyn (1965) that the tanned shells/capsules of freely deposited platyhelminth eggs confer protection on embryos swallowed by predators.

Hatching

This raises the question as to how hatching takes place. A tanned flatworm egg, like that of *E. soleae*, has a single circular suture separating a lid or operculum from the rest of the eggshell. The larva (oncomiracidium) escapes by dissolution of the thin layer of cement holding the operculum in place. Observations by Kearn (1975) indicate that hatching in *E. soleae* is brought about by a proteolytic (protein-digesting) hatching fluid produced by two pairs of gland cells located ventrally in the head of the fully developed oncomiracidium. Hatching in *E. soleae* begins when the surface cilia on the body of the oncomiracidium begin to beat. This imparts rotation to the oncomiracidium about its longitudinal body axis. The head, which is located beneath the operculum, slowly rotates at a speed of about 6 s per revolution and during rotation the openings of the hatching glands are adjacent to the opercular discontinuity. Presumably the secretion that these glands produce slowly weakens the opercular cement until the seal finally breaks and the operculum becomes detached. The oncomiracidium squeezes through the opercular opening aided by traction generated by the continually beating cilia.

The tanned egg capsules of the parasitic turbellarian *Syndisyrinx franciscanus* usually contain 6–8 fertilised eggs (zygotes) (Shinn, 1983). Hatching takes place in a similar way to the shelled eggs of *E. soleae*. However, the turbellarian capsule has numerous sutures arranged in a reticulum. Shinn and Cloney (1986) observed that prior to hatching the sutures are severely weakened by the activities of the contained larvae and on hatching the capsule shatters into many pieces. Shinn and Cloney found evidence to suggest that the embryos secrete a hatching enzyme since intact capsules are unaffected by externally applied trypsin (a powerful protein-digesting enzyme) but when capsules are cut open and then incubated in trypsin, the sutures become weakened. Shinn and Cloney hypothesised that the ability of sutures to resist enzymatic attack from the outside but not from the inside, is the result of differences in the chemical properties of the cement in outer and inner parts of the sutures.

The digenean *Fasciola hepatica* (sheep liver fluke) has a tanned egg and contains a ciliated larva (miracidium) destined to infect a mollusc. Surprisingly, the hatching mechanism of *F. hepatica* has little in common with that of *Entobdella soleae*. They share the first step, which involves activation of the enclosed miracidium or oncomiracidium. Thereafter their hatching events are very different. As noted above *E. soleae* uses glands to dissolve the cement holding the operculum in place, while the miracidium of *Fasciola* is unable to enter the opercular end of the ovoid egg because it is occupied by a so-called viscous cushion (Fig. 3). After activation

Fig. 3 Egg of the digenean *Fasciola hepatica* containing a fully developed larva (miracidium). e – eye; o – operculum; sa – sac; vc – viscous cushion. Scale bar: 25 μ m. Redrawn from Smyth, J.D., Halton, D.W., 1983. *The Physiology of Trematodes*, second ed. Cambridge: Cambridge University Press.

of the miracidium, the cushion and two separate thin-walled sacs expand, increasing the pressure progressively inside the shelled egg until the opercular seal ruptures (Wilson, 1968). Wilson offered arguments against the notion that a hatching enzyme weakens the opercular cement in *Fasciola*.

The Uterus

Many platyhelminths have no uterus, the oötype opening directly or via a short tube to the outside (Fig. 2). Tanning needs to be completed while the shelled egg or capsule is in the oötype, but the disadvantage of this is that, while the shelled egg/capsule occupies the oötype, further egg/capsule assembly cannot take place. The provision of a uterus (secondary uterus of Shinn (1986); see above) permits the shelled egg/capsule to leave the oötype and complete tanning of the shell or capsule wall, thereby making way for the assembly of the next shelled egg/capsule. Shinn (1986) found that the maximum rate of capsule production in the turbellarian *Wahlia pulchella* was 5–15 times greater than that of other umagillids lacking a uterus. Thus, acquisition of a uterus for the storage of shelled eggs/capsules opens up an evolutionary pathway that has been exploited in remarkable ways by many platyhelminths. This is well illustrated by the relationship between polystomatid monogeneans parasitising amphibious hosts (frogs and toads).

Amphibious vertebrates such as frogs and toads (anurans) present a formidable challenge for potential parasites because transmission cannot take place while the host is on land. The biology and ecology of the monogenean polystomatid parasite *Pseudodiploporchis americanus* from the urinary bladder of the North American desert toad (*Scaphiopus couchii*) has been studied in depth by Tinsley and co-workers over many years and provides some of the most exciting and interesting discoveries in Parasitology (see references in Kearn (1998)). *Scaphiopus couchii* is almost exclusively terrestrial, spending most of the year (9–10 months) buried in the desert sand (see references in Kearn (1998)). The toads emerge from the sand to spawn following torrential rain, which generally occurs on only 1–3 nights of the year, creating temporary pools in the desert. Remarkably, *P. americanus*, inhabiting the urinary bladders of these toads, is ready to take advantage of this very brief window of opportunity, since their uteri are packed with eggs containing fully developed oncomiracidia. As the toads enter the spawning assemblies in the pools, the larvae, each enclosed by

a thin sac possibly produced by the uterus, are released and hatch. The ciliated oncomiracidia attach themselves to half-submerged toads, crawl over the toad's skin above the water surface and enter the nostrils. They begin development in the respiratory sac then migrate through the gut to the urinary bladder. The parasites then mature and accumulate infective larvae in the uterus, so that they are ready one year hence for the next annual spawning event. This phenomenon is known as ovoviviparity.

Growth of the embryos in the uterus of *P. americanus* is substantial and the sac (shell?) enclosing each embryo stretches to accommodate the gradual increase in size. However, there are only two or three vitelline cells accompanying the early embryo and they are unlikely to make a significant contribution to the nutrition of the growing embryo. It seems more likely that food reaches the growing embryo via the wall of the uterus. A protective shell is no longer a requirement for eggs like those of *P. americanus* that hatch as soon as they leave the host. The parasite needs to accommodate as many eggs as possible in the uterus and this can be better achieved by having flexible 'shells' rather than rigid tanned shells.

The functions of the vitellarium in *P. americanus* have now been superseded and the organ is greatly reduced, the space being made available for the huge uterus. The germarium retains its anterior position with the uterus posterior to it (Tinsley, 1978, in [Kearn \(1998\)](#)). Another polystomatid, *Eupolystoma anterorchis*, from the urinary bladder of a South African toad (*Bufo pardalis*), is also ovoviviparous, storing shelled eggs in a large uterus while the toad is on land. However, *E. anterorchis* creates space for the large uterus in a different way from *Pseudodiplorchis* by posterior relocation of the germarium and lateral displacement of vitelline and testicular follicles. The implication is that ovoviviparity has evolved independently in *Pseudodiplorchis* and *Eupolystoma*.

Use of the uterus to store shelled eggs reaches unprecedented levels in the cyclophyllidean tapeworms. Their elongated bodies (strobilae) ([Fig. 1\(F\)](#)) are sub-divided into 'segments' termed proglottids each of which contains a complete set of reproductive organs including a uterus. The cyclophyllidean uterus is blind-ending, branched and contains thousands of fully developed eggs with complex untanned shells. Ultimately each gravid (egg-filled) proglottid becomes detached from the strobila, passes out in the host's faeces and bursts liberating and scattering the eggs. If eaten by the next host in the life cycle the untanned egg-shell is vulnerable and is digested releasing the living tapeworm larva.

In some cyclophyllideans profound changes affect the uterus as it fills with shelled eggs. New structures called paruterine organs may appear, into which the eggs are passed from the uterus. The function of these organs is unclear.

The Male Reproductive System

The male copulatory organs of monogeneans deserve special attention because of their remarkable diversity, greatly surpassing the rather conservative organs in the tapeworms (Cestoda) and the digeneans (Trematoda). The male gonad (testis) gives rise to a special gonoduct, the vas deferens, which transports mature sperm distally and often expands to form a seminal vesicle where sperm is stored.

Penis or Cirrus

The distal end of the vas deferens is modified to form an intromittent organ, which may be a penis or a cirrus. Of the two, penises encompass an enormous range of copulatory organs. In its simplest forms the penis may be a protrusible muscular organ or the sclerotised (hardened) tubular termination of the male gonoduct, but these organs are often accompanied by a remarkable range of accessory sclerites ([Fig. 4](#)) and accessory glands, the latter often misleadingly called 'prostate glands'. A cirrus has the ability to turn inside out as the organ is protruded, like the finger of a glove ([Fig. 5](#)).

The distal region of the vagina may be sclerotised, or specialized in other ways, in order to receive the male copulatory organ and to ensure that separation does not occur during mating.

Auto-Infection and Self-Insemination

The prolonged storage of shelled eggs in the uterus, as in *Eupolystoma* spp., is but a short step from hatching of some of these eggs and auto-infection (see [Kearn \(1998\)](#)).

Self-insemination has been reported in juveniles belonging to the monogenean genus *Benedeniella* (see [Kearn and Whittington \(1992\)](#)). Because of protandry the long male copulatory organ (cirrus) is able to enter the uterus and penetrate as far as the oötype, without meeting any obstructing female traffic in the opposite direction ([Fig. 6](#)). *Benedeniella* spp. also have a prominent vagina ([Fig. 6](#)), which has the potential to support self-insemination or cross-insemination when the female system comes on line and the uterine route can no longer be used. However, it has been shown experimentally that self-insemination does not occur in the related monogenean *Entobdella soleae* (see [Kearn and Whittington \(2015\)](#)).

Using a different experimental approach, [Dinh Hoai and Hutson \(2014\)](#) showed that self-insemination does occur in the monogenean *Neobenedenia* sp., a parasite of the commercially important fish barramundi (*Lates calcarifer*). This was achieved by infecting the uninfected hosts each with a single oncomiracidium. The isolated parasites reached maturity in 10 days and laid eggs that successfully infected specimens of *L. calcarifer* with second and third generation isolated parasites. The self-insemination route followed by this species of *Neobenedenia* is not known – there is no vagina – but the finding of the penis deflected into the parasite's own uterus in an individual of the related *Neobenedenia melleni* (see [Whittington and Horton \(1996\)](#)) suggests that selfing may occur via the uterine route in species of *Neobenedenia*.

Self-insemination was also observed by [Ogawa et al. \(2014\)](#) in *Neobenedeniagirellae* (see below).

Hypodermic/Transtegumental Insemination

Macdonald and Caley (1975) observed unilateral mating repeatedly in the monogenean *Diclidophora merlangi* but found no vagina. The muscular penis papilla armed with hooks is attached ventrolaterally to the mating partner, but this site does not correspond with the opening of the uterus. Macdonald and Caley came to the surprising conclusion that the tegument (surface covering) is breached in some way, either by the penis hooks or perhaps by a histolytic (tissue-digesting) glandular secretion, permitting sperm to enter the body. Macdonald and Caley showed that after penetration the sperms travel between the body cells (parenchyma) and, remarkably, navigate in some way to a storage organ, the seminal receptacle. No mutual (bilateral) insemination or self-insemination was observed.

Fig. 5 The partly everted cirrus of the monogenean *Trimusculotrema heronensis*, photographed alive in dorsal view. Scale bar: 250 μ m. Reproduced from Whittington, I.D., Kearns, G.C., 2008. *Trimusculotrema heronensis* sp. nov. (Monogenea, Capsalidae) from the skin of the pink whipray *Himantura fai* (Elasmobranchii, Dasyatidae) from Heron Island, Queensland, Australia. *Acta Parasitologica* 53, 251–257). With permission from De Gruyter.

More typical hypodermic impregnation may occur in the monogenean *Gastrocotyle trachuri* (see Llewellyn (1983)). The parasite has a tubular penis sclerite and no vagina. Llewellyn suggested that the penis passes through the tegument and deposits sperm in the parasite's tissues. Sperm was found inside the body but mating was not observed.

Spermatophores and Pseudospermatophores

The monogenean *Entobdella soleae* produces jelly-like spermatophores with a centrally located mass of sperm. The way in which the living animal transmits these spermatophores has been observed and recorded by Kearns (1970). Mutual exchange takes place and each spermatophore is attached externally to the co-copulant in the region of the relatively small ventral opening of the vagina. Contractions of the parasite's body in the region of the attached spermatophores serve to draw the sperm into the vagina, the rest of the spermatophore being discarded.

A novel method of impregnation by way of spermatophores has been described by Ogawa *et al.* (2014) in another monogenean *Neobenedenia girellae*. Each spermatophore consists of two components, a proximal portion that stains with the pink dye eosin and a distal, thin-walled portion containing sperms. Both portions are enclosed within a thin outer casing. There is no vagina. The spermatophores are implanted externally (dorsally), apparently at random sites, mainly on the posterior half of the body. Sperms were identified within the parenchyma (body tissues), in the vicinity of the attached spermatophores. Sperms gain access to these internal sites via damage to the surface layers (tegument), most likely inflicted by the penis. Ogawa *et al.* suggested that sperms reach the female tract via the vitelline ducts. Self-insemination was observed, as well as unilateral and mutual (bilateral) insemination.

Many monogeneans have elongated, encased structures which are assumed to be spermatophores (Fig. 7), but there is potential for confusion here because spermatophores and so-called pseudospermatophores are similar in appearance and lodged in the same site, the vaginal opening (Fig. 7). Pseudospermatophores contain no sperm and are put in place after the deposition of sperm in the vagina and withdrawal of the intromittent organ. It is assumed that, by blocking the vaginal opening, pseudospermatophores prevent leakage of freshly received sperm. Pseudospermatophores may also prevent sperm from a second challenging individual entering the vagina and competing with sperm already present from a previous mating.

Permanent Cross-Insemination

The ultimate development in response to the need for cross-insemination occurs in diplozoid monogeneans. Permanent insemination is achieved by complete tissue fusion between two young parasites (**Fig. 8**). The reproductive ducts of the two fused individuals connect up, ensuring a potentially uninterrupted supply of sperm for each partner from the co-copulant and saving energy that would have to be expended on repeat matings. Curiously, the sperms of *Diplozoon* lack flagella and cannot swim, a condition which has come about perhaps because there is no longer a need for strong swimming to compete with other sperms to achieve fertilisation (see Justine, 1995, in Kearn (1998)).

The excretory systems and the marginal hooks as a basis for the systematics of *Gyrodactylus* (Trematoda, Monogenea). *Archiv für Zoologi* 23, 1–235.

Asexual Reproduction

Cyrodactylid monogeneans are protogynous (female system matures first) and viviparous, giving birth to living young (Fig. 9). Some species of *Cyrodactylus* may reach ages and densities that favour sexual reproduction but others do not reach this level and are likely to reproduce asexually (references in [Kearn \(1998\)](#)).

A few families of tapeworms (cyclophyllideans) with two-host life cycles have acquired the ability to multiply asexually in the intermediate host by budding.

In digeneans the question is whether the sequential production of sporocysts, rediae and cercariae in the mollusc host involves an asexual process (polyembryony, budding) or is a modified sexual process (see [Kearn \(1998\)](#)). Also it is widely accepted that digenean reproduction involves the phenomenon of germinal segregation (germinal lineage), a process that appears to be unparalleled in other parasitic platyhelminths as far as is known (see references in [Kearn \(1998\)](#)). After fertilisation, the cell undergoes unequal cleavage, producing a somatic cell and a smaller propagatory cell. The former gives rise to the body of the miracidium and the latter persists as a germ cell. In other words a lineage of cells is established from the original fertilised cell and is conserved and maintained separately from the somatic cells throughout the life history phases (references in [Kearn \(1998\)](#)).

Comparative Reproductive Biology in Nematodes

Beatriz Moreira-Pinto and Andre Pires-daSilva, University of Warwick, Coventry, United Kingdom

© 2018 Elsevier Inc. All rights reserved.

Introduction

Nematoda is one of the most diverse taxa, with nearly 26,000 described species. Nematodes live in almost any kind of environment, being on rotting organic matter, hot springs, desert, ocean, inside of animals (including humans) and plants, and even in deep mines 3 km down in the Earth. Free-living species feed mostly on bacteria, but also on fungi, algae and other nematodes. Their size vary from 100 μm to 14 m, and their reproductive output ranges from just a few eggs to up to two million eggs a day per individual. Some small (~ 1 mm long) nematodes, such as *Caenorhabditis elegans*, are very prolific because in addition of producing many progeny per individual by self- and cross-fertilization (up to 685 eggs in their lifetimes), they also have a short life cycle (3 days from egg to adult at 25°C). Thus, a single individual has the potential to give rise to many million descendants within a few weeks (Bird and Bird, 1991).

Most nematodes are sexually dimorphic, with sexes that differ in relative size, shape of the gonad, shape of the tail and presence/absence of a vulva (Fig. 1). Sexual dimorphism can be sometimes extreme, such as males of *Trichosomoides crassicauda*, which live inside the female uterus. Males use mechano- and chemosensory organs located in the head and tail to track the opposite sex and inseminate it by internal fertilization. Some nematode species might even have three sexual forms, the third being a self-fertilizing hermaphrodite. *Heterorhabditis bacteriophora* and *Rhabditis* sp. SB347, which have three sexual forms, reproduce by self-fertilization, crosses between hermaphrodites, as well as by crosses between males and females (Kanzaki et al., 2017).

The great diversity in the various aspects of nematode reproduction provides a great challenge to summarize in a short article. Here we focus on some recent studies in comparative biology of reproduction in nematodes. The phylogenetic relationships of nematodes covered in this article are depicted in Fig. 2.

Evolution of Modes of Reproduction

Nematodes have various types of modes of reproduction (Table 1). Dioecy is the most common, followed by parthenogenesis, androdioecy and trioecy. In some nematodes, reproductive modes can alternate between generations, so that a uniparental generation (hermaphrodite or parthenogenetic female) never meets the males of the biparental generation. In *Rhabdias*, for example, the parasitic generation is a hermaphrodite that lives inside the lung of amphibians and reptiles. The progeny of *Rhabdias* hermaphrodites develop into adults outside the host, becoming the male/female (dioecious) generation. Similarly, the mammal parasite *Strongyloides* facultatively alternates between a parasitic parthenogenetic generation and a free-living dioecious generation (Streit, 2008). Thus, in some species the three sexual morphs do not occur simultaneously in the same location. In trioecious species like *H. bacteriophora* and *Rhabditis* sp. SB347, however, hermaphrodites, females and males do occur simultaneously (Kanzaki et al., 2017), and males of those trioecious populations can facultatively cross with females or hermaphrodites.

The transition between reproductive modes has occurred multiple times during nematode evolution, across the nematode phylogenetic tree (Fig. 2). In the genus *Caenorhabditis*, the androdioecious species *C. elegans*, *C. briggsae* and *C. tropicalis* independently evolved the ability to self-fertilize from ancestral species that were dioecious (Fig. 2). The convergence in phenotype was achieved by distinct molecular mechanisms. The same direction of change, from dioecy to androdioecy, is also observed in

Fig. 1 Differences between sexual morphs in free-living nematodes. The hermaphrodite and female have two gonad arms, while the male gonad is composed of a single testis that runs the length of the nematode. The hermaphrodite produces and stores sperm for self-fertilization. The male tail is short and blunt and has mechanosensory and chemosensory neurons, while the female/hermaphrodite has a thin and long tail.

Fig. 2 Phylogenetic relationships and sexual morphs of nematodes covered in this article. The nematode phylogeny has five major clades, four of each are depicted here.

Table 1 Types of reproductive mode

Type	Definition
Dioecious	Sexual reproduction between males and females. In the nematode literature, is sometimes referred as 'gonochorism'.
Androdioecious	Sexual reproduction by self-fertilization of hermaphrodites, or by crossing between hermaphrodites and males.
Trioecious	Sexual reproduction by self-fertilization, or between males and females, or between males and hermaphrodites.
Parthenogenetic	Asexual reproduction only by females. Sometimes males are present, but do not contribute with genetic material to the next generation.

Pristionchus, but it can also occur in the reverse direction. *Oscheius dolichuroides*, for example, is a dioecious species derived from an androdioecious ancestor (Fig. 2) (Denver et al., 2011).

In principle, a single mutation that turns the sperm inviable in hermaphrodite, or that abolishes the production of sperm in hermaphrodites, is sufficient for the evolution of dioecy from androdioecy. In contrast, in the evolution androdioecy from dioecy, at least two mutations have to occur: (1) a mutation that briefly masculinizes the germline of the female for the production of sperm; (2) a mutation that activates the sperm in the female. Thus, the occurrence of these mutations in a population gives rise to the intermediate trioecious mating system. Trioecy is extremely rare in nematodes, and is known only in some undescribed free-living nematodes and in the insect parasite *H. bacteriophora*.

The evolution of self-fertilization facilitated the colonization of new environments by single individuals. Interestingly, *H. bacteriophora* and *Rhabditis* sp. SB347 independently evolved the coupling of dauer larva formation to the development of adult hermaphrodites (Kanzaki et al., 2017). Dauer is a facultative larval stage that resists to lack of food, detrimental environmental conditions, and has a series of adaptations for migration. By coupling dauer with hermaphroditism, these nematodes species further potentiated the ability to colonize new habitats.

Evolution of Sex Determination Systems

Sex determination is one of the fastest evolving developmental systems (Bachtrog *et al.*, 2014). This is reflected in the diversity of sex determining systems in the animal kingdom, which can be mediated by chromosomal and environmental factors. Predictions of sex determination in nematodes have been drawn from cytological studies, which indicate that most species perform chromosomal sex determination. However, the diminutive size of nematode chromosomes in many cases makes the karyotypic interpretation difficult, resulting in conflicting reports.

The most common type of chromosomal sex determination system in nematodes is in which the heterogametic sex is the male (Pires-daSilva *et al.*, 2007). In this case, sex chromosomes are denoted X and Y (e.g., in *Brugia malayi*). Thus, females are XX and males are XY. Several nematodes do not have a second sex chromosome, and in this case the sex determination system is denoted XX:XO. Heterogametic males, as the name implies, produce gametes with two kinds of gametes: XY males, produce equal proportions of sperm with an X chromosome and sperm with Y chromosome; XO males produce equal proportions of sperm with an X chromosome and the other half harboring only autosomes. The XX:XO system is thought to be derived from the XX:XY system, whereby the Y chromosome was lost during evolution.

In other groups of animals with a XX:XY system, sex is determined by either a dominant male-determining factor, or by the ratio of X chromosomes relative to autosomes (in this case, the Y chromosome has no role in sex determination). Unfortunately, the mechanisms that trigger the sex determination in nematodes with a XX:XY system are not known, probably because most of those species are parasitic and thus difficult to manipulate genetically.

The best characterized sex determination system is in *C. elegans*, which relies on an XX:XO system. The balance of X chromosomes to autosomes (X:A) determines sex in this nematode, with the X causing a feminizing effect and autosomes a masculinizing effect. Thus, *C. elegans* with two sets of autosomes and two of sex chromosomes (2A:2X) are hermaphrodites and 2A:1X animals are males. The XX:XO system is also present in other *Caenorhabditis* species (e.g., *C. remanei* and *C. briggsae*) (Stothard and Pilgrim, 2003). Genes in the X chromosomes and autosomes act in a dose-dependent manner to regulate the transcription of the masculinizing gene *xol-1* (XO lethal). The transcription of *xol-1*, which codes for a kinase, leads to a series of signal-transduction events that ultimately represses the transcription factor *tra-1* (*transformer-1*). In XX animals, *tra-1* promotes female development mainly by repressing expression of male-specific genes. Despite the rapid evolution of genes involved in sex determination, their function seems to be at large extent conserved in the soma.

The evolution of hermaphroditism, which independently occurred three times in *Caenorhabditis* (Kiontke *et al.*, 2004), required modifications of the sex determination in the germline of XX animals (Ellis and Lin, 2014). In these animals, there is a transient masculinization of the germline for the production of sperm, followed by the production of oocytes. The evolution of this trait in *C. elegans* and *C. briggsae* involved the recruitment of different sets of genes, independent recruitment of the same genes, and also the modification of the function of sex-determining genes (Baldi *et al.*, 2009).

Although *C. elegans* and *C. briggsae* hermaphrodites are XX and thus expected to produce only XX self-progeny, they may produce XO males in some rare (~0.1%) instances. This occurs because of X chromosome non-disjunction, in which abnormal chromosome pairing and synapsis during meiosis generates gametes containing only autosomes (nullo-gametes). Thus, a nullo-sperm, when fertilizing an X-bearing oocyte, generates a male. In other nematodes with XX:XO system, XX animals may generate male self-progeny by different mechanisms. In the *Rhabdias* genus, for example, XX hermaphrodites produce equal proportions of XX female and XO self-progeny. This occurs by a modification of the meiosis during hermaphrodite spermatogenesis, in which half of the gametes removes the X chromosome of the meiotic cell. In *Strongyloides papillosus*, the parthenogenetic XX female generates male progeny by a process called chromosome diminution. Interestingly, in this nematode the ancestral X chromosome became incorporated into an autosome (Nemetschke *et al.*, 2010). During meiosis of oocytes destined to become males, the region corresponding to the ancestral X is eliminated in one of the chromosomes, thus generating an XO animal.

Male heterogamy is the most common sex determination system in nematodes, and no examples for female heterogamy (ZZ/ZW system) are known. In haplo-diploids, which are known to occur only in oxyurid nematodes, unfertilized eggs develop into males and diploid fertilized eggs develop into females. In species with environmental sex determination, crowding, immune status of the host, and temperature are factors that regulate sex determination.

Evolution of Different Types of Gametes

The mitotic germline usually is located in the terminal part of the testis, followed by cells at more advanced meiotic stages as they become closer to the proximal part of the gonad (Chu and Shakes, 2013). The generation of a male gamete involves the meiotic division of a primary spermatocyte to generate two secondary spermatocytes, which divide to form four secondary spermatids (Fig. 3). Those spermatids undergo differentiation by shedding unnecessary contents for sperm function (e.g., microtubules, actin, endoplasmic reticulum, translation machinery). The activation of spermatids, which refers to the conversion of the spherical, quiescent spermatids into the mobile, mobile spermatozoa, is triggered by extracellular signals. Sperm activation results in ameboid-like cells, which form pseudopodia by the assembly and disassembly of a nematode-specific protein named Major Sperm Protein (MSP). Thus, contrary to sperm of insect and mammals, nematode sperm lack cilia or flagella.

Comparative studies on the evolution of sperm have been performed in the *Caenorhabditis* genus, in which sperm size ranges from 3 to 281 μm^2 (Vielle *et al.*, 2016). Interestingly, the size of the sperm correlates with their competitive advantage

Fig. 3 Spermatogenesis. (A) The division of primary spermatocyte in meiosis I gives rise two secondary spermatocytes. After the division of secondary spermatocytes into four cells in meiosis II, unnecessary cytoplasmic components are discarded into a vesicle (grey circle). (B) After the activation of the spermatid, MSP (purple) polymerizes to form the pseudopods.

Fig. 4 Sperm competition in hermaphrodites. The larger male sperm (yellow) outcompetes the smaller hermaphrodite sperm (blue) to fertilized the oocyte. The color of the egg corresponds to the product of fertilization between a self and male sperm.

(LaMunyon and Ward, 1998). In androdioecious species, in which both sexes produce sperm, the male sperm is usually larger and outcompetes the hermaphrodite sperm (Fig. 4). However, size alone is probably not the only cause for the difference in competitiveness. It is still unclear whether this competitive edge of the larger sperm is due to their greater speed due to the larger pseudopod, greater adhesion to the wall of the hermaphrodite uterus, or greater capacity to dislodge the smaller hermaphrodite sperm.

Some species of nematodes produce more than one kind of sperm. Sperm with size dimorphism, for instance, have evolved independently in a few nematode lineages. In *Steinernema tami*, miniature sperm aggregate around giant sperm, which serve as transportation device in the female uterus (Yushin *et al.*, 2007). Males of *Rhabditis* sp. SB347 also produce two kinds of sperm, a functional X-bearing sperm and a non-functional nullo-X sperm (Shakes *et al.*, 2011). Thus, those XO males generate practically only XX progeny when crossing with the opposite sex. The production of two kinds of sperm in *Rhabditis* sp. SB347 is caused by a modification of meiosis and the differentiation of the spermatids. In the final spermatocyte division, the mitochondria and other cytoplasmic components necessary for sperm function (e.g., MSP) co-segregate with the X chromosome. Thus, unnecessary cytoplasmic components segregate to the nullo-X spermatid, generating a non-functional gamete.

How Sexes Find Each Other

Nematodes have mechanosensory and chemosensory organs that allow them to find the opposite sex in order to reproduce. Males and females of the free living *Panagrolaimus rigidus*, for example, when separated by a cellophane barrier, move towards individuals of the opposite sex but not to the ones of the same sex. These experiments suggest the release of sex-specific attractants, the sex pheromones. Some of these pheromones are small molecules containing a dideoxysugar connected to a fatty acid chain. The name of these pheromones, known as ascarosides, derives from *Ascaris lumbricoides*, a nematode in which these chemicals were first

characterized. The biological activities of ascarosides are determined by the length of the chain of side carbons, modifications of the dideoxysugar sugar, and the blend of the different ascarosides. Some of these blends elicit different behaviors, such as inducing dauer formation in early larvae.

In *Panagrellus redivivus*, both males and females produce mutually-attracting ascarosides. In the trioecious species *Rhabditis* sp. SB347, with a mating system thought to be intermediate between dioecy and androdioecy, females attract males more efficiently than hermaphrodites. The same pattern is observed in androdioecious species as *C. elegans* and *C. briggsae*, in which hermaphrodites are weaker in attracting males when compared to females of sister dioecious species (e.g., *C. remanei*). Interestingly, *C. remanei* males immobilize females by the secretion of paralyzing chemicals in the seminal fluid, facilitating copulation. Males of *C. remanei* or *C. elegans* cannot paralyze *C. elegans* hermaphrodites, indicating that hermaphrodites are refractory to these male chemicals and can escape from mating. These results suggest that hermaphrodites have evolved adaptations to avoid mating with males.

In *C. elegans*, all neurons have been mapped. Males and hermaphrodites share many of the head sensory neurons, but only males display mate searching behavior. Since *C. elegans* males and hermaphrodites share some of the same neurons, how is the sex-specific behavior triggered? The searching behavior is mediated by the expression of the neuropeptide PDF-1 in males, which is heightened when they are well-fed. Overexpression of PDF-1 in hermaphrodites, however, does not elicit a mate searching behavior in them, indicating that this neuropeptide acts through a sexually dimorphic circuit despite sharing the same neurons.

The male-attracting behavior is mediated by male-specific CEM neurons, as well as the core sensory olfactory neurons AWA, AWC and ASK. It is still not clear how many or which receptors are involved in the male attracting behavior, but a few such as the TRPV (transient receptor potential vanilloid) channel are starting to be discovered.

Glossary

Acanthocephala A group of dioecious, obligatory sexual, parasitic worms that are evolutionarily related to rotifers.

Amictic (Synonymous: asexual; apomictic thelytoky) in the life cycle of monogonont rotifers, reproduction by diploid, ameiotic parthenogenesis. Female with this mode of reproduction. Phase of the life cycle of monogonont rotifers with this mode of reproduction.

Apomictic thelytoky See *amictic*.

Arrhenotokous parthenogenesis Parthenogenesis where unfertilized eggs develop into males.

Bdelloidea One of three classes of rotifers with a wormlike body, distinguished from the other two classes by reproducing exclusively asexually.

Cyclical parthenogenesis (Synonymous: heterogony) the alternation of generations between asexual and sexual facultative modes of reproduction.

Diapause A dormant period of arrested growth and development characterized by an encysted stage with greatly slowed metabolism.

Diapausing egg See *diapausing embryo*.

Diapausing embryo (Synonymous: resting egg; diapausing egg) a resistant (encysted), thick-walled, diploid embryo arrested in an early stage of development, with highly sculptured outer surfaces usually produced by sexual reproduction in monogonont rotifers.

Eutely (eutelic) A condition in metazoans in which there is a predetermined number of cells and typically no cell division after birth.

Haplodiploidy (haplodiploid) Sex-determination system in which males are haploid and develop from unfertilized eggs; related to *arrhenotokous parthenogenesis*.

Heterogony See *cyclical parthenogenesis*.

Intracytoplasmic lamina (ICL) A filamentous layer of protein embedded within the cells comprising the body wall of rotifers and acanthocephalans.

Micrometazoans Multicellular animals small enough to require a microscope to visualize.

Mictic (Synonymous: sexual) in the life cycle of monogonont rotifers, reproduction involving meiosis. Females reproducing mictically produce males from unfertilized eggs and diapausing eggs from fertilized eggs. Phase of the life cycle of monogonont rotifers with this mode of reproduction.

Mixis (Synonymous: sexual) the phase of the life cycle of monogonont rotifers where oogenesis occurs via meiosis, producing haploid ova and sperm and subsequent fertilization.

Monogononta One of three classes of rotifers, distinguished from the other two by having a single gonad and reproduction by *cyclical parthenogenesis*.

Oviparous Females that lay eggs that hatch outside the body. Reproduction with this characteristic.

Ovoviviparous Females that lay eggs that hatch within the body with subsequent birth of live offspring. Reproduction with this characteristic.

Parthenogenesis Reproduction evolved from sexual reproduction where fertilization is not involved in the embryo production.

Quorum sensing Responding to chemical signals related to population density, synchronizing activities like sexual reproduction, where individual fitness requires coordination with other individuals.

Resting egg See *diapausing embryo*.

Seisonidea One of three classes of rotifers, distinguished from the other two by reproducing only through sex.

Sexual induction signal (Synonymous: mixis induction signals) in the life cycle of monogonont rotifers, environmental signal inducing sexual reproduction in facultatively sexual individuals. E.g., a protein released into the environment by *Brachionus* females that triggers sexual reproduction.

Subitaneous egg In the life cycle of rotifers, a thin-walled, rapidly-developing egg produced by asexual females that immediately hatches into a young, diploid female that is either asexual or sexual.

Introduction

Description

Rotifers (Rotifera: wheel-bearers) includes >2000 species of minute (ca. 0.05–3 mm), short-lived, micrometazoans dwelling mostly in lakes, ponds, and streams and coastal marine habitats (Fig. 1). Three main features separate rotifers from other micrometazoans. (1) The apical end usually bears a ciliated region (corona) that may be embellished by various folds, lips, or ear-like extensions. (2) The ventral region of the pharynx (mastax) holds a complex series of articulating hard jaws comprised of chitin and scleroprotein. (3) Cells comprising the body wall form a syncytium that is variously thickened by a filamentous layer of protein termed the intracytoplasmic lamina (ICL). When the ICL is thin the body wall is flexible; in its thickest form it is rigid.

From the dawn of microscopy in 1600s, rotifers have been the object of intense study. Current knowledge on anatomy is well summarized by Fontaneto and De Smet (2015) who review modern work in imaging science, including the anatomical details revealed by the latest techniques in light and electron microscopy, and immunohistological staining. Wallace *et al.* (2015) also provide information on rotifer general biology, as well as their ecology and evolution.

Rotifers have direct development and are eutelic – there is no cell division after development has been completed – so females are born with their lifetime supply of oocytes. They are distinguished among other animals because the major clades (Seisonidea, Bdelloidea, and Monogononta) reproduce via obligate sexuality, obligate asexuality, and facultative sexuality, respectively (Fig. 2).

Phylogeny and Taxonomy

Phylogenetic relationships of rotifers with other groups and between the major rotifer clades are not yet resolved. Rotifera is still considered a phylum. However, based on morphological and molecular characteristics, Acanthocephala (a group of dioecious, obligatory sexual, parasitic worms) appears to be closely related. All share the unique feature of the ICL and there are similarities in the ultrastructure of the spermatozoa. Molecular analyses using mitochondrial 16S rRNA and nuclear 18S rRNA also argue for a close relationship. A possibility is that the phylogenetic branch including Bdelloidea and Monogononta is closer to

Fig. 1. Female and male *Brachionus* species. From Figure 13.2 in Wallace, R.L., Snell, T.W., Smith, H.A., 2015. Phylum rotifera. In: Thorp, J.H., Rogers, D.C. (Eds.), Thorp and Covich's Freshwater Invertebrates. Waltham, MA: Elsevier.

Acanthocephala than to Seisonidea. If so, rotifers would not be a monophyletic group. Nevertheless, here we consider only the classical three rotifer clades, each of which being considered a class, although their taxonomical rank varies among authors.

Comprising a single family of only four species, seisonids are dioecious, diploid, wormlike animals that are larger than other rotifers (≤ 3 mm). The sexes are of similar size and morphology, but females have paired ovaries that lack vitellaria; males lack specialized copulatory organs.

Bdelloids possess a relatively uniform morphology characterized by a wormlike body and paired ovaries with vitellaria. They are smaller than seisonids (0.1–1.6 mm), but richer in species (~ 350 species). Males have never been reported in the class. This and their genomic architecture strongly support that they reproduce exclusively by parthenogenesis (Flot *et al.*, 2013).

Monogononts comprise the largest class of rotifers (~ 1600 species). Having a body size that ranges from 0.05–2.0 mm, their body form varies. Some are worm-like, some are ellipsoid-like, and others are dorso-ventrally or laterally flattened. While all monogononts are believed to be dioecious, males have never been observed in many species. The archetypal life cycle is characterized by relatively long periods of female parthenogenesis that occasionally are broken by spates of sexual reproduction (i.e., cyclic parthenogenesis). While females are diploids, males are haploids and usually are structurally reduced.

Ecology

Bdelloids usually are found in sediments, among plant debris, or crawling along surfaces. Some species inhabit the water films in soils or on mosses. Adults are capable of tolerating extreme environmental conditions, including freezing and desiccation (anhydrobiosis). Monogonont are benthic, free swimming, or sessile. Their occurrence is mainly restricted to pools, ponds, lakes, coastal lagoons and estuaries. Seisonids are marine rotifers that live as epibionts on small crustaceans. Rotifers are widely distributed geographically. Although small, they play important roles in aquatic habitats. They feed on a variety of bacteria, algae, and protists and then, in turn, are fed upon by protists, other rotifers, small crustaceans, and fishes. Rotifers possess high reproductive potential and may attain high population densities (occasionally > 5000 individuals per liter), thus making them important components in aquatic food webs.

Modes of Reproduction

Asexual Reproduction in Bdelloidea and Monogononta

Parthenogenetic production of daughters is the obligate mode of reproduction in bdelloids and the most common mode in monogononts (Fig. 3). During their embryological development, diploid females produce diploid oocytes by mitosis; two equational divisions produce two polar bodies and give rise to a diploid embryo. Thus, parthenogenetic production of daughters is believed to be ameiotic (i.e., apomictic thelytoky) and to lack crossing over. Thus, barring mutations, all offspring are females and genetic clones of their mothers. Oocytes are embedded in a tissue called the vitellarium that synthesizes yolk for the developing embryos and transfers it via a cytoplasmic bridge. Once embryos are fully loaded with yolk, they are deposited outside the female via an oviduct. Females of some species (e.g., *Brachionus*) carry their embryos until hatching attached by a slender thread. Others lay their

Fig. 3 Cyclical parthenogenesis of monogonont rotifer. Notice that (1) the fraction of sexual daughters is zero in absence of a sufficient sexual induction signal, so that a phase of exclusively asexual proliferation exists, and (2) some diapausing embryos may not respond to the hatching cues, they constituting a diapausing embryo bank. Fine line drawings courtesy of Africa Gómez and María José Carmona.

embryos on a substrate (e.g., *Philodina*) or simply drop them where they sink to the bottom (e.g., *Proales*). Embryos are typically deposited at the single cell stage before cleavage begins. In oviparous rotifer species, all embryological development takes place outside the mother. Some species (e.g., *Asplanchna*) are ovoviparous and give birth to fully formed live young. With a few exceptions reported, the asexual embryos are subitaneous (i.e., no dormancy). Both birth-flow and birth-pulse (i.e., those laying in clutches) species exist.

Cyclical Parthenogenesis in Monogononta

One of the most intriguing features of the life cycle of monogononts is their ability to engage in both asexual (amictic) and sexual (mictic) reproduction (Fig. 3). This life cycle is designated cyclical parthenogenesis (also, heterogony) because most reproduction is asexual (described above), with episodic bouts of sexual reproduction (mixis). Sexual reproduction starts with production of sexual females by asexual mothers. These two types of females are morphologically indistinguishable. Thus, the first visible sign of sexual reproduction in rotifer populations is the appearance of unfertilized sexual females who produce males (Fig. 4) (Wallace *et al.*, 2015), which occurs in response to specific environmental triggers. Researchers have investigated these environmental sexual induction signals for more than 50 years and examples of sexual reproduction induction by photoperiod, diet, or population density can be found in the literature. Many other intrinsic and extrinsic factors – such as age, genotype, salinity, temperature, and diet – influence the proportion of sexual daughters, but these usually are not regarded as key factors triggering mixis. The list of species responding to population density signals is growing and progress has been made over the last decade in identifying these chemicals. The process is understood as a case of quorum sensing (Kubaneck and Snell, 2008), widely known in bacteria, but its description in rotifers was the first for animals.

The general model for sexual reproduction in response to crowding is that rotifers excrete a chemical into the medium that accumulates to a threshold concentration, triggering a switch in oocyte maturation pathways to enable meiosis. Diploid mothers (i.e., sexual females) produce haploid embryos via meiosis that develop into haploid males if unfertilized (arrhenotokous parthenogenesis) or diploid diapausing embryos if they are fertilized. If a sexual female is inseminated when young, she will only produce diapausing embryos; otherwise, she will only produce males. Therefore, sex determination is haplodiploid.

Rotifers excrete a variety of compounds into their medium, producing 'conditioned medium', the chemical composition of which has been analyzed (Snell *et al.*, 2006). The signal triggering sexual reproduction was shown to be a protein in *B. manjavacas* and designated the mixis inducing protein (MIP) (Snell, 2017). It functions as a pheromone and *B. manjavacas* populations are exquisitely sensitive to the MIP signal, initiating sexual reproduction at population densities as low as 70 females L^{-1} .

Fig. 4 Rotifer cyclical parthenogenesis in *Brachionus*. (a) Asexual female. (b) Male-producing sexual female carrying haploid eggs. (c) Diapausing embryo. Bars $\sim 50\ \mu\text{m}$. SEM photomicrograph (c) courtesy of Hendrik Segers.

The accumulation of the MIP to threshold concentrations triggers a cascade of events that results in oocyte maturation via meiosis rather than mitosis. The MIP pheromone is thought to bind to a receptor on the surface of females, initiating a signal transduction cascade that is regulated by hormones. These have not been characterized for rotifers, but the presence of steroid receptors for progesterone and estrogen-like molecules and presence of metabolic pathways for steroid synthesis suggest that steroids play an important role in these signaling pathways (Snell, 2011).

Male embryogenesis apparently parallels that of the female embryo to a certain point of organogenesis (e.g., in *Asplanchna*, formation of the cerebral-ganglion). At that point certain organs either degenerate (stomach) or fail to develop altogether (mastax). Spermatogenesis begins late in development of the unfertilized, haploid egg and includes, as its major features, cell elongation, flagellar differentiation, and development of the nuclear membranes. Developing along with the sperm are atypical germ cells that eventually degenerate. In recently matured males, sperm outnumber the atypical cell type by a ratio of 2:1. As they mature, the atypical cells extrude immobile, rod-like structures approximately $2 \times 10\text{--}15\ \mu\text{m}$ in size. These rods appear to facilitate passage of sperm through the female integument (see below). Except for a few species, most male monogononts have degenerate guts and do not feed; thus they are dependent on energy provided by their mother during oocyte development, and have shorter lifespan than females (Fig. 1).

Mating is another key step in sexual production (Fig. 5). Mature males cannot detect females from a distance and rely on random encounters to locate mates. Models of typical population densities and swimming speeds demonstrate that male encounters with fertile females during their short lifespans are sufficient to make mating probable. Upon encountering a conspecific young female, males of most monogonont species engage a stereotypical behavior called circling. They swim tight circles around females, skimming their body surface so that they maintain contact with their corona. Chemoreceptors on the male corona detect surface glycoproteins on females allowing conspecific identification. Brachionid males preferentially mate with young females. The chemical structure of this surface glycoprotein-mating signal has been identified and the underlying gene described. The role of this mate recognition protein in the development of rotifer reproductive isolation and speciation has been investigated (Gribble and Mark Welch, 2012).

Insemination usually is accomplished by hypodermic impregnation. Sperm are transferred by penetration of the female body wall by the male penis, but in a few species sperm are deposited directly into the cloaca. After introduction into the body cavity of females, they fuse with a mature oocyte in the ovary. The result of this fertilization is a diploid embryo that undergoes 5–6 rounds of cell division and then arrests its development at the 40–60 cell stage. The embryo, which is encased in a resistant shell and provisioned with yolk that enables dormancy, is a diapausing embryo (also called resting egg or diapausing egg). In this state the embryo is metabolically inactive and resistant to freezing and desiccation.

Diapausing embryos can remain dormant for decades, and are typically deposited in the sediments. Experimental work indicates that hatching from diapause is influenced by a variety of factors including temperature, light, salinity, and oxygen concentration. Hatching also is stimulated when diapausing embryos are exposed to UV light, dilute solutions of hydrogen peroxide, and certain prostaglandins. It has been hypothesized that active oxygen, either generated by UV photolysis or from the peroxide itself, oxidizes fatty acids within the dormant embryo. These fatty acids induce production of prostaglandins, and then initiate hatching.

Experimental studies on the monogonont life cycle are concentrated on a few model species. The remaining information has been recorded in more-or-less systematic field surveys, but that may be biased by variation in species abundance and distribution. Even though loss of sex is common in long-term laboratory populations, cyclical parthenogenesis is believed to be the ancestral state in monogononts. Out of a total of 30 monogonont families, males have been observed in 25 cases and diapausing embryos in 26. Only in two families (Birgeidae and Clariidaea) have none of these features been reported.

Fig. 5 Copulation in the monogonont rotifer as described in *Brachionus*. Other mating behaviors have been described in rotifers; these include male mate-guarding of unhatched mictic embryos and, apparently, cannibalism of their male consorts by newly mated mictic females.

Ancient Asexuality in Bdelloidea

Ancient asexuality in Bdelloidea was proposed a long-time ago because males had not been observed in either natural or laboratory populations, and meiosis has never been reported. Indeed the evidence against unobserved, rare sex is now much stronger and is supported by molecular signatures for lack of sexuality. Genomic analysis of the bdelloid *Adineta vaga* shows it is tetraploid and its genome comprises anciently duplicated segments and less divergent allelic regions, the latter sometimes being found on the same chromosome. Hence, meiotic pairing is not possible. Interestingly, transposable elements account only for 3% of the assembled genome sequence (Flot *et al.*, 2013).

It is now accepted that bdelloids have persisted for at least tens of millions of years and diversified into >300 species without engaging in sexual reproduction. This lack of the putative advantages of sex (i.e., mutation purge and/or adaptation to environmental change) is a unique case among animals and challenges evolutionary biologists to investigating the mechanisms and environments that make their evolutionary success possible.

Obligate Sexuality in Seisonidea

Seisonids reproduction is bisexual with a sex ratio of ~1:1. Gametogenesis takes place by ordinary meiosis with production of two polar bodies. Males and females are about the same size. The U-shaped, male genital apparatus consists of a pair of large, elongate testes and a large seminal vesicle where sperm receive additional processing. Two sperm are attached together, tightly rolled, and encysted with a secretion; the product is an encysted sperm pair (ESP) $\approx 1.5 \times 8 \mu\text{m}$. The ESP is moved through the vas deferens and into the cloaca. Mating in seisonids has never been observed, but workers suggest that the male transfers the ESP to a spatulate groove on the head and subsequently attaches it to the female's genital region. Unlike what is seen in the monogononts the embryo does not enter a dormant phase; i.e., it is subitaneous.

Reproductive Patterns and Their Adaptive Implications

Life-table experiments performed with bdelloids and monogononts show that life span, age at maturity and maximum age-specific fecundity are strongly affected by temperature, diet quality and quantity, salinity, pH, and toxicants. At 23–27°C, asexual offspring are produced by 2-day old mothers, potential lifetime fecundity ranges 10–40 offspring per female mostly concentrated in the early age classes, and lifespan is in the range of 5–40 d. In optimal laboratory conditions fecundity rate ranges from 0.2 to 1.2 offspring per female per day, and the populations can double their density every 1.5–2 d. In monogononts, age-specific fecundity is higher for

male-producing sexual females and lower for diapausing embryo-producing sexual females, as compared to asexual females. These differences correspond with allocation of resources per embryo. Lifetime production of diapausing embryos is only 5–40% that of asexual embryos. Generally reproduction is faster at higher temperatures over a range of 10–35°C.

Most rotifer habitats are suitable for population growth only temporarily. Rotifer populations in lakes are ecologically specialized so that they proliferate during specific seasons. Other rotifers inhabit temporary habitats such as rock pools and the water films of moist soils, mosses, and lichens. Rotifers are adapted to these recurrent, more or less predictable, adverse periods by producing resistant dormant stages with arrested metabolism. These resistant stages also function in dispersal. As expected from theoretical considerations, in both monogononts and bdelloids the resistant phases of the lifecycle are coupled with increases in genetic variation. In monogononts this is accomplished through recombination that occurs during sex. In bdelloids it arises from DNA breakage and repair during desiccation and results in large-scale horizontal gene transfer from a variety of prokaryotes and eukaryotes (Gladyshev *et al.*, 2008).

Many bdelloids have the ability to undergo anhydrobiosis: desiccate as an adult (xerosome) and as an embryo (xerooum), and to remain metabolically inactive, resuming their life cycle where they left off upon rehydration (Ricci, 2001). Few animals have the ability to engage in this amazing process. Desiccated individuals can survive for years in this state (Fig. 6). Not all adults survive desiccation, but bdelloid reproductive performance is not negatively affected by anhydrobiosis when metabolism is resumed. During desiccation, DNA breakage often occurs and bdelloids possess exceptional DNA repair mechanisms. This breakage is hypothesized to favor horizontal gene transfer, which accounts for about 8% genes in their genome unlike most other animal species (Gladyshev *et al.*, 2008). DNA repair is proposed to occur using collinearly paired chromosomes as homologous templates. These processes might compensate for their lack of recombination and enables adaptation and diversification similar to sexually reproducing animals (Boschetti *et al.*, 2012).

The growing season of a typical monogonont rotifer population starts when diapausing embryos hatch in response to warming temperatures and increased light level. The females hatched from diapausing embryos may have special features. For example, in *Polysartha* hatchlings lack paddle-like appendages that are usually present in females and are used to escape predators. In some *Brachionus* species, the females hatching from diapausing embryos are insensitive to mixis induction signals. This insensitivity persists, but is diminished, in the following generations, providing evidence for a transgenerational, epigenetic effect. Each female hatched from a diapausing embryo establishes a new clone (i.e., a lineage of genetically identical individuals, excluding mutations) via asexual reproduction. Such asexual reproduction results in fast population growth, an advantageous trait when growing in seasonally suitable or ephemeral habitats. When sexual reproduction is initiated, asexual females produce both sexual and asexual daughters. Thus, both modes of reproduction overlap. The diapausing embryos produced as a result of sexual reproduction fall to the sediment and where they can remain dormant for decades. Some sexual, diapausing embryos remain dormant only for a few days, whereas others will be dormant until the next growing season or for many years. The latter contributes to the diapausing embryo bank, a genetic and demographic buffer for the population. Mortality and hatching rates of diapausing embryos in the sediment are poorly known. In sediments chronologically structured, the density of viable embryos declines exponentially with depth. Long-term survival enables resurrection ecology of rotifers by hatching the diapausing embryos of past populations.

Sexual reproduction in monogononts has both benefits and costs (Stelzer, 2011). Regarding the later, (1) evidence suggests that the two-fold cost of sex is fully operative in rotifer populations. Theoretical evolutionary modeling predicts that half of the sexual females should be male-producers and half should be diapausing-embryo producers, the few empirical studies testing this being supportive of this prediction. As a result, two-fold more diapausing eggs could be produced if they could be produced asexually.

Fig. 6 Bdelloid adult (xerosome, left) and embryo (xerooum, right) in the anhydrobiotic state. Scanning photomicrograph courtesy of Giulio Melone.

(2) As male-female encounter occurs randomly, sex might be rare in low-density populations. (3) As populations composed of multiple clones, inbreeding is potentially important. (4) Resource allocation per unit is higher in diapausing embryos than in asexual embryos. (5) Metabolic arrest in diapausing embryos increases generation time. Thus, early sex might result in few male-female encounters and, by decreasing the rate of current population growth, could produce suboptimal exploitation of the environment. In contrast if delayed, sex could occur when the habitat is becoming unsuitable for sexual reproduction, diminishing diapausing embryo production. Consequently, the timing of sex in cyclically parthenogenetic life cycles is a critical component of fitness.

Three selective factors have been proposed to shape timing of sex in monogononts (Serra *et al.*, 2004): (1) habitat deterioration, (2) male-female encounter, and (3) resource demand. As a cue, population density might anticipate (#1), favor (#2), and occur in conditions favorable for reproduction (#3). Nevertheless, some diapausing embryos may hatch when population density is high. Proliferation of the resulting clones is much favored if they are temporarily insensitive to the mixis signal, as observed in *Brachionus*. Interestingly, laboratory populations evolve early sex in conditions mimicking ephemeral and fluctuating habitats (Smith and Snell, 2012). This last finding is consistent with the correlation between environmental unpredictability and propensity of sex found in natural populations. It is regarded as a conservative bet-hedging strategy, preventing the catastrophic effect of unexpectedly short growing seasons.

Besides enabling diapause, sex increases genetic variation, which is needed to drive natural selection and promote adaptation to novel conditions. Experimental monogonont populations in a novel environment evolve and can achieve an adaptive steady state in less than 2 months, which is equivalent to a few dozen generations (Becks and Agrawal, 2012). During adaptation they increase their rate of sex, but this rate declines to a plateau when the selection pressure ceases. Rotifer experimental systems where the diapause response is not a confounding factor (e.g., hatching rate of diapausing embryos is not dependent on the experimental treatment) offer an exceptional opportunity to explore the evolution of sex.

Applied Reproduction

Rotifers have proven useful in environmental toxicology and aquaculture. In environmental toxicology production of diapausing embryos by brachionids has enabled development of variety of toxicity tests that do not require culturing to supply test animals (Rico-Martinez *et al.*, 2013). These methods have allowed rotifer toxicity tests to be deployed widely without need to master the technical skills of culturing rotifers. Diapausing embryos of *B. plicatilis*, *B. manjavacas*, and *B. calyciflorus* now are commercially available and are readily shipped globally. All can be hatched in standard media within 24 h, yielding animals that are physiologically uniform for use in toxicity tests. Standard protocols have been developed using endpoints like survival, reproduction, swimming velocity, ingestion, and gene expression using well-characterized strains. Reproduction is especially important because it is one of the most sensitive endpoints and is a good estimator of chronic toxicity. The ecological significance of even small reductions in rotifer reproduction over many years has been demonstrated (Snell and Serra, 2000). As little as a 5% reduction in population growth rate can approximately double the probability of extinction for a population.

Hatchlings from diapausing embryos are all females who initiate asexual reproduction within 24 h of their birth. By 48 h, a typical female at 25°C will produce 5–10 daughters that can be counted and used to estimate the intrinsic growth rate (r), a statistic with considerable significance in ecology. Rapid asexual reproduction permits 2–3 generations of population growth to be quantified in one week, making the rotifer reproductive test one of the shortest for any animal. As a result of the convenience, speed, and sensitivity of rotifer reproductive tests, they have been widely employed to estimate chronic toxicity in fresh and marine waters.

A second industry that employs rotifers is aquaculture. Most marine fish larvae begin feeding on zooplankton of a size that is determined by the gape of their mouths. Rotifers have proven reliable and cost-effective as live feeds in the larviculture of many commercially important fish and crustacean species (Hagiwara and Yoshinaga, 2017). This is because marine *Brachionus* have a simple diet of microalgae, reproduce rapidly, are tolerant of a wide range of temperatures and salinities, and are tolerant of high population densities in mass cultures. Scientists in many countries have intensely investigated production by both marine and freshwater species of the genus *Brachionus*, how they can be manipulated to produce more rotifers per liter more efficiently. Most marine fish hatcheries worldwide have a small cadre of scientists and technicians dedicated to maintaining rotifer mass cultures. Aquaculture scientists have reported much of what is known about effects of diet, temperature, salinity, and pH on brachionid reproduction. Rotifer culture remains an active area of research, with investigations into how to enrich rotifers so that their nutritional quality closely matches the needs of fish larvae, identification of new rotifer species suitable for mass culture that are small enough to be ingested by young fish larvae, improving the stability of mass cultures to avoid crashes, and optimizing bio-processes of mixing and waste removal in mass cultures.

Mollusca

Toshie Matsumoto, National Research Institute of Aquaculture, Mie, Japan

© 2018 Elsevier Inc. All rights reserved.

Mollusc is one of the most diverse groups in the animal kingdom and includes oysters, scallops, clams (Bivalvia), abalones, snails, slugs (Gastropoda), nautilus, squids and octopuses (Cephalopoda). Many bivalves, gastropods and cephalopods are economically valuable species and play an important role in the fisheries industries of many countries. Molluscs are mostly marine, but also include freshwater and terrestrial species. They burrow or crawl on rocky, sandy, and muddy substrata, become cemented to the surface, or swim. They have adapted to these environments and have developed diverse varieties of reproductive strategies. One of the primary reasons for the success of molluscs as a dominant phylum is the diversification of their reproductive systems. Although the reproductive strategies used by molluscs are indeed variable, some of the physiological mechanisms must be conserved in the phylum. Therefore, it is expected that the genes and proteins known to be involved in the fundamental processes of reproduction in other phyla are conserved and have physiological functions also in molluscs.

The genome sequencing and transcriptome analyses of various molluscan species including the sea hare *Aplysia californica*, the snail *Lymnaea stagnalis*, the slipper snail *Crepidula fornicata*, the snail *Ilyanassa obsoleta*, the owl limpet *Lottia gigantea*, the mussel *Mytilus galloprovincialis*, the Pacific oyster *Crassostrea gigas*, the scallop *Patinopecten yessoensis* and the clam *Meretrix meretrix*, have been performed for the survey of the conserved genes related to reproduction. Through bioinformatic analyses the reproduction-associated genes have been identified, and knowledge on the molecular mechanisms of reproduction in molluscs is gradually being accumulated. Similarly, draft genome of the pearl oyster *Pinctada fucata* was released and utilized to obtain structural information of genes and proteins involved in various reproductive processes of bivalves by screening reproduction-related genes reported from other molluscan species (Matsumoto *et al.*, 2013). In the article the reproduction-related genes of *P. fucata* were described based on 6 categories: germline differentiation; sex determination; gonad development; oocyte maturation and spawning; fertilization; others. Of these categories, this article focuses on *vasa* for germline differentiation, egg-laying hormone and caudo-dorsal cell hormone for spawning, and gonadotropin-releasing hormone for gonad development, because they are identified from several molluscan species. Other categories on molluscan reproduction are reviewed in another articles in this book (vitellogenesis, spermatogenesis, endocrine control of reproduction and genetics-oyster). More comprehensive reviews on the physiology of reproduction appear in Saleuddin and Mukai (2016).

Bivalvia

The majority of bivalves (clams, mussels, oysters, and scallops) are gonochoristic but several hermaphroditic species are known (e.g., the egg cockle *Fulvia mutica*, *Pecten albicans*). In bivalves, the gonad appears as a transient anatomical structure that develops during the reproductive season, when the body mass can more than double. The gonadic tissue consists of a series of connected tubules organized in sack-like structures, generally called genital tubules or acini, in which germ cells differentiate centripetally from the external border (the wall) to the center (the lumen), where mature gametes accumulate in the spawning season. The mature gametes are released from each gonad, and fertilization is external. After completion of spawning, unspawned gametes are reabsorbed and the gonad is disassembled. Consequently, the sex of the animal can be assessed only in the reproductive season, while it is not possible during the sexual rest, when there are no gametes. The gametogenic development of bivalves is usually classified into several stages such as undifferentiated, early developing, late developing, ripe, spawning and spent stages. At undifferentiated stage, the gonadal area is largely filled with the connective tissue cells, and genital tubules contain only undifferentiated germ cells (Fig. 1(a)). During developing stage, oögonia or spermatogonia develop from undifferentiated cells and divide actively, and gonadal area expands and invades the connective tissue (Fig. 1(b)).

Sexually reproducing metazoans generally segregate their germline away from their somatic tissue before they make gametes; in *Drosophila*, *Caenorhabditis elegans* and mouse, this occurs during embryogenesis. In these animals, maternal factors required for germline formation are localized in a posterior region of egg cytoplasm and are inherited into the primordial germ cells. Members of the *vasa* and *nanos* gene families are important for the specification and development of the germline in diverse animals. The *vasa* gene, firstly characterized in *Drosophila*, encodes a member of the DEAD (Asp-Glu-Ala-Asp) box family of ATP-dependent RNA helicases. In *Drosophila*, Vasa protein is detected in the germline throughout the development; it is incorporated in pole cells, expressed zygotically in migrating pole cells, found in the embryonic gonads and expressed in the germline during oogenesis. Pole cells of a *Drosophila* embryo contain maternal Nanos and start zygotic expression of *nanos* during their migration into the gonads. Vasa and Nanos are highly conserved among metazoans and many orthologues have been identified from various invertebrates and vertebrates.

In molluscs, *vasa* ortholog was first characterized in the Pacific oyster *Crassostrea gigas*, and isolation of *vasa* orthologs in other molluscs is continuing. The discovery of transcripts of a *C. gigas vasa* homolog led to the conclusion that *vasa* is present also in molluscs, and that it can be used as a germ line marker. A *vasa* homolog was also documented in *Mytilus galloprovincialis* and *Pinctada fucata*, at the transcript level, and in *Ruditapes philippinarum*, *Mya arenaria*, *Anadara kagoshimensis* and *C. gigas*, at the protein level (Milani *et al.*, 2017). Vasa expression during the gonad rebuilding of these bivalves was immunohistologically observed to verify its presence from undifferentiated germ cells to mature gametes using antibodies produced against *vasa* homolog of

Fig. 1 Histological sections of the Pacific oyster *Crassostrea gigas*. (a) At undifferentiated stage the gonadal area is largely filled with the connective tissue cells. Genital tubules contain only undifferentiated cells. (b) At ripe stage genital tubules filled with full-grown oocytes enlarge and invade the surrounding connective tissue. Scale bar=1 mm.

R. philippinarum. In these species, the genital tubules are located close to the gut (intestine), extended inside the connective tissue. The gut epithelium consists of a monolayer of cells. In the basal side of the epithelium, vasa-stained cells are present. Stained cells with the same morphology are also dispersed in the connective tissue. At the beginning of gametogenesis, many stained cells are present in the connective tissue. During gamete maturation, acini are full of many differentiating germ cells and mature gametes. In female acini, the oocytes at the end of vitellogenesis show a faint vasa staining, while smaller oocytes show a stronger vasa staining. The male mature acini occupied by sperm show low or none of vasa staining. The immunohistological data obtained support a conserved mechanism of proliferation of “primordial stem cells” among the simple columnar epithelium of the intestine, as well as in the connective tissue, contributing to the seasonal gonad reconstitution. Vasa immunolabeled cells within the intestinal wall are commonly found across bivalves, the proliferation of vasa-stained cells in the intestinal epithelium is correlated to the stage of gonad maturation. The presence of germ cell precursors in the gut epithelium appears to be a feature in common with model organisms, such as mouse, fruit fly, and human.

In gastropods, *vasa* and *nanos* orthologs have been isolated from the snail *Ilyanassa obsoleta* and the abalone *Haliotis asinina*. In *I. obsoleta*, both *vasa* (mRNA) and *nanos* (mRNA and protein) are uniformly distributed during early cleavage and then become selectively expressed in the 4d lineage. In *H. asinina*, both *vasa* and *nanos* mRNA are detected in the mesodermal region of the larva. Furthermore, *nanos* is required to maintain the fate of the 4d lineage in *Ilyanassa*; knockdown of the *nanos* ortholog activity in the embryo clearly blocked normal development of the mesendodermal blast cell lineage derived from the 4d cell.

Gastropoda

All gastropods have a single gonad, and sexes are separate among most of members of prosobranchs but the majority of gastropods (opisthobranchs and pulmonates) are hermaphrodites. In these animals, both male and female gametes are produced in a single ovotestis and these are carried by a hermaphroditic duct to the carrefour/fertilization pouch where, following fertilization (self or cross), the eggs are coated by the perivitelline fluid secreted by albumen gland. They then pass through the female tract where the eggs are coated in a jelly mass and/or put in capsules. Most of the hermaphroditic species do reproduce by cross-fertilization. Since these animals have their male and female gonopores located on different parts of the body, mating chains or rings can form. In such a chain, the frontmost individual acts only as a female, the last individual only as a male, and each individual in between acts as male to the partner directly in front of it and female to the partner directly in its back. The role of neuropeptides in egg laying behavior has been extensively investigated in *Aplysia* and *Lymnaea*.

In the sea hare *Aplysia*, ovulation and spawning are triggered by a neuropeptide, the egg laying hormone (ELH), synthesized and released from the neuroendocrine bag cell neurons in the abdominal ganglia (Fig. 2(a)). Injection of an abdominal ganglion extract from *A. californica* induced egg laying and associated behaviors in several other *Aplysia* species. The bag cells are a pair of cell clusters, and each group contains about 400 cell neurons. When the animal is ready to lay eggs, a neural signal is initiated in the cerebral ganglia. This signal is relayed to the pleural ganglia, and then transmitted to the bag cell neurons. After the neural signal activates bag cell neurons, ELH is secreted. The large preprohormone of ELH is processed into mature ELH together with the shorter peptides, bag cell peptides (BCPs) which are also involved in the control of the egg laying. In addition, the exocrine atrial gland in the reproductive tract of *Aplysia* expresses multiple ELH-precursor-related genes, including one encoding peptide A and another encoding peptide B. Peptides A and B induce the electrical discharge of bag cells *in vitro*. Comparison of the structures of ELH precursor and the ones for the atrial gland peptide A and B (ELH related precursor A and B, ELHRa and b) revealed their close structural similarity. The ELHRs contain an ELH domain which is cleaved to produce ELH. The ELH and the ELHR genes form the egg-laying hormone gene family.

The egg-laying of *L. stagnalis* is regulated by neurosecretory system quite similar to the bag cell system of *A. californica*. The administration of cerebral ganglion extract from *L. stagnalis* also caused spawning of snails of the same genus. In *L. stagnalis* ovulation and spawning are controlled by a neuropeptide called caudo-dorsal cell hormone (CDCH) secreted from the caudo-dorsal cells (CDC) in the cerebral ganglia (Fig. 2(b)). These cells are located in two paired clusters of about 50 neurons each in the cerebral ganglia. Egg-laying consists of a sequence of behavioral events beginning with a rest period when the animal ceases to locomote, then a turning phase characterized by counterclockwise shell movements and high frequency rasping to clean the substrate, followed by oviposition and a final phase called inspection when the snail moves along the length of the egg-mass brushing it with lips and tentacles. Egg laying in *Lymnaea* is triggered by a discharge of spiking activity in CDCs, the resting phase. During this discharge the CDCs express several peptides such as CDCH and four kinds of caudo-dorsal cell peptides (CDCP), encoded on the CDCH-gene. ELH and CDCH, or BCP and CDCP, share 50%–70% similarity in amino acid sequence. CDCH also initiates the actual ovulation, which is followed by the fertilization and packaging of the released ripe eggs by the female accessory glands. During turning phase the animal starts locomoting again, turns its shell back and forth and rasps the surface. This process continues as long as the passage of eggs through the female tract is registered. The size of egg mass is independent of the injected dose of CDCH. Oviposition starts when the egg mass emerges from the female gonopore and is fixed to the substrate. This phase usually lasts about 10 min during which the animal continues rasping, stops shell turning and hardly locomotes. When the egg mass has been deposited, the animal crawls along the mass, without rasping or shell turning, before leaving it behind; this is referred to the inspection phase. When egg laying starts, ripe oocytes are ovulated from the ovotestis and fertilized in the fertilization pouch. Adult *L. stagnalis* can lay egg masses at a frequency of at least one mass per week, and such masses contain an average between 50 and 150 eggs depending on the individual's body size. *L. stagnalis* that are older than 300 days usually show a decline in egg production. Other factors that inhibit egg laying are starvation and dirty water. Spiking activity of the CDCs is not affected by dirty water. However, during starvation the CDCs become hyperpolarized, which elevates the threshold for egg laying.

In abalones *Haliotis rubra* and *Haliotis asinina*, using the same antibody, ELH-immunoreactivity was detected in neurons of the cerebral and pleuropedal ganglia, and in the ovary. The positive cells were numerous in order of the pleuropedal, cerebral and visceral ganglion. In addition, the intense reactivity was detected in the follicular and granular cells adjacent to mature oocytes in the ovary. In contrast, gastropods (*Aplysia* and *Lymnaea*) ELHs were also detected in the female reproductive tract (the oothecal gland, muciparous gland, pars contorta, and ovotestis, respectively) but none have been reported in the ovarian tissue.

Fig. 2 Central nervous system of *Aplysia* (a) and *Lymnaea* (b). AG, abdominal ganglion; CG, cerebral ganglion; PeG, pedal ganglion; PIG, pleural ganglion; PaG, parietal ganglion; VG, visceral ganglion; CC, cerebral commissure; BC, bag cell; CDC, caudo-dorsal cell.

ELH and CDCH share relatively high structural similarity, and therefore CDCH is now often referred to as the ELH of *L. stagnalis*. In molluscs, presence of the ortholog genes of ELH have been reported from the abalone *H. rubra*, the limpet *Lottia gigantea*, the oyster *C. gigas* and the pearl oyster *P. fucata*. In *C. gigas* and *P. fucata*, ELH-related peptides are duplicated on the respective precursors. The amino acid sequence alignment of the two predicted ELH domains with the ELH domain of other ELH family peptides indicated structural similarity. But the overall structures of these ELH peptide precursor were different from those of *Aplysia* ELH, ELHR and *Lymanaea* CDCH. For instance, BCP or CDCP peptides are not found on the precursor proteins of *L. gigantea*, *C. gigas* and *P. fucata*. In the phylogenetic analysis, *L. gigantea*, *C. gigas* and *P. fucata* ELH form a separate clade to *Aplysia* and *Lymanaea* ELH (Stewart *et al.*, 2014).

Cephalopoda

Sexes are separate in cephalopods and sexual dimorphism is evident in almost all species. Males are smaller in a few species, possess hectocotylus arms that are used for the transfer of spermatophores into the female's body. Many cephalopod males exhibit an array of courtship behaviors during mating. Little is known about the life span of cephalopods. The majority of them are semelparous, in which death follows after the reproductive period in both sexes. The common octopus *Octopus vulgaris* normally breeds in its second year; the females lay eggs and care for them without feeding and then die shortly after the eggs hatch. Death occurs owing to a secretion from the optic gland, a pair of small bodies on the optic tracts connecting the optic lobes with the central regions of the brain. However, if the optic glands are removed from brooding females, the animals abandon their eggs, resume feeding, and the programmed death is delayed for a considerable period. Sexual maturity in *O. vulgaris* is always associated with enlargement of the optic gland. Implantation of the glands from sexually mature individuals to immature recipients induces precocious maturation. Optic gland implants between males and females are equally effective. Sexual maturation of the female octopus is hormonally controlled by a pair of optic glands. The gland regulates various reproductive events such as proliferation of gonadal cells and yolk-protein synthesis.

In vertebrates, gonad maturation is primarily regulated by the hypothalamus-pituitary-gonadal axis. Gonadotropin-releasing hormone (GnRH) is a neuropeptide originally identified to be synthesized in the hypothalamus of mammals. It is transported from nerve endings in the hypothalamus to the adenohypophysis where it stimulates the release of the gonadotropins, thus serves as a key regulator of reproduction of vertebrates. The vertebrate GnRH is a 10-mer peptide with N-terminal pyro-Glu and C-terminal Pro-Gly-NH₂ structure.

GnRH in cephalopods was initially demonstrated by immunohistochemistry with anti-chicken GnRH antibody; octopus GnRH-containing neurons were diffusely distributed in various lobes in the octopus brain, including the subpedunculate and the posterior olfactory lobes. Because GnRH-containing nerve process are found in the optic tract and optic gland, it is suggested that GnRH neurons stimulate optic gland activity, which results in gonadal maturation. The presence of molluscan ortholog of GnRH has been clarified in the octopus *O. vulgaris* which was followed by the identification of GnRH-like peptides in the swordtip squid *Loligo edulis*, the common cuttlefish *Sepia officinalis*, the sea hare *A. californica*, the limpet *L. gigantea*, the scallop *P. yessoensis*, the oyster *C. gigas* and the pearl oyster *P. fucata*. The precursor structure of vertebrate GnRHs is well conserved also in the structure of the molluscan counterparts deduced from cDNA information. Purified octopus GnRH-like peptide has two amino acid insertions at the N-terminal and C-terminal Pro-Gly-NH₂ structure that is critical to gonadotropin-releasing activity in vertebrates. Primary structures of the other two cephalopod GnRHs were predicted to be identical to octopus GnRH. Thus, cephalopod GnRHs are 12-mer peptides whereas for the other molluscan GnRHs, the C-terminal glycine residue is missing, and hence the deduced mature peptides are 11 amino acids long without C-terminal amidation. In *C. gigas*, two types of GnRH peptides (Cg-GnRH-a and Cg-GnRH-G) were characterized by mass spectrometry, and possessed an identical amino acid sequence but differed in the presence (Cg-GnRH-a) or absence (Cg-GnRH-G) of the amidation at the C-terminal. As for the physiological function of GnRH in molluscs, octopus GnRH-like peptide and scallop GnRH-like peptide are suggested to control the gonad development. In the chiton *Mopalia sp.*, exposure to dilutions of lamprey GnRH1 or tunicate GnRH-2 in sea water induced spawning which suggested pheromone-like function of GnRH in this species. In contrast, GnRH of the sea hare *A. californica* had no effects on the acute activation of various aspects of reproduction in this species.

Glossary

Albumenotrophy Yolk external to the embryo (e.g., in cocoon fluid) that is a food source during development.

Chaetae Bristle-like structures, also called setae.

Clitellum Glandular, annular swelling of the epidermis; secretes material to form a cocoon.

Cocoon Protective case, covering of an egg mass or immature stage.

Epididymis Coiled part of the vas deferens.

Epitoky Process by which an asexual individual (the atoke) is transformed into or gives rise to one or more sexual individual(s) called epitokes that produce eggs and sperm. Epitokes leave the bottom for the purpose of reproduction.

Errant (Errantia) Polychaetes are grouped into two large clades, Sedentaria and Errantia, originally based on their locomotory patterns.

Gonochoric Eggs and sperm produced in separate individuals.

Gonopore External opening of the male and female reproductive organs.

Hermaphrodite Individual with both male and female sexual systems.

Lecithotrophic Egg yolk provides all nourishment; larvae are non-feeding.

Metatrochophore Polychaete larva that displays segmentation. Feeding or non-feeding. Stage at which settling and metamorphosis occur in some species.

Nectochaete Polychaete pelagic larva that uses parapodia as locomotory organs. Feeding or non-feeding. Stage at which settling and metamorphosis occur in some species.

Oocyte Immature female gamete that undergoes meiosis, giving rise to an egg.

Oogonia Germ cells that give rise to oocytes by mitotic division.

Operculum A structure that seals or closes a tube; lid-like cover on the opening of a cocoon.

Parapodia Lateral, segmental outgrowths that usually bear chaetae.

Parthenogenesis The development of an individual from an unfertilized egg.

Planktotrophic Feeding on the plankton.

Predaceous Consuming other animals for nutrients.

Prostate gland An elaboration of the sperm canal that secretes a prostatic solution.

Protandry Type of hermaphroditic sex determination in which the male reproductive state precedes female. Individual produces sperm then, later in life, eggs.

Protogyny Type of hermaphroditic sex determination in which the female reproductive state precedes male. Individual produces eggs then, later in life, sperm.

Sanguivorous Consuming blood for nutrients.

Spermatheca A genital structure in which sperm is received and may or may not be stored.

Spermatophore A packet of sperm for transfer from male to female.

Spiral cleavage A type of cleavage in which blastomeres appear to be produced in a spiral pattern as opposed to a radial one. Spiral cleavage is the basic cleavage pattern of protostomes; radial cleavage is the basic pattern of deuterostomes.

Testis sac A membranous sac around the testis, seminal vesicle and the funnel to the vas deferens.

Trochophore Top-shaped swimming larva that is the common uniting factor of the trochozoan clade (part of the Lophotrochozoa clade). Usually with three bands of cilia, the prototroch, metatroch, and telotroch. May be feeding or non-feeding.

Tubicolous Living in a tube.

Vas deferens Sperm duct leading away from a testis, carries sperm to the male pore.

Vitellogenesis The production of yolk.

Introduction

Annelids are segmented worms that occupy marine, freshwater and terrestrial habitats. Historically, the Phylum Annelida was subdivided into the polychaetes (mostly marine worms), oligochaetes (e.g., earthworms) and hirudinids (leeches), but more recently the oligochaetes and hirudinids have been combined into the Superclass, Clitellata. Also, modern molecular phylogenies have reclassified a number of related phyla (i.e., Echiuroidea, Sipuncula, Siboglinidae (Pogonophora and Vestimentifera)) as derived polychaetes.

The general annelid body plan is relatively simple, comprising an anterior mouth and posterior anus separated by a variable number of segments. Polychaetes display segmental parapodia (lateral extensions which can be quite ornate) containing many bristle-like structures called chaetae, while clitellates (excluding leeches) have reduced, segmentally-iterated chaetae that occur in bundles. Leeches are unique in having a fixed number of 32 segments and specialized anterior and posterior suckers.

Reproduction in annelids ranges from fertilization in the open water to asexual fragmentation and parthenogenesis. Here we consider reproductive strategies in the two major annelid groups, the Polychaeta and the Clitellata.

Polychaeta

Polychaete worms, with few exceptions, are marine and estuarine. They are ubiquitous in the ocean, burrowing and hunting in the benthos, crawling on algal covered rocks, living in self-made tubes, or swimming in the water. Polychaetes are as diverse as any other major animal group and exhibit many variations in their reproductive modes. A few species are being developed as model organisms. *Capitella teleta* (Hill and Savage, 2009; Seaver, 2016), whose genome has been sequenced (see Relevant Websites section), *Platynereis dumerilii* (Fischer et al., 2010; Zantke et al., 2014; see Relevant Websites section) and members of the genus *Ophryotrocha* (Thornhill et al., 2009) are all rich sources of information. Bioinformatics programs allow many comparisons and data are accumulating. Since more than 10,000 polychaete species have been described, however, an obvious need exists for further investigation.

Polychaetes reproduce and disperse in many ways. Although sexual reproduction (fertilization of eggs by sperm) is most common, some display remarkable asexual reproductive capabilities.

Sexual Reproduction

Most polychaetes are gonochoric with sex determination usually being genetic, although not well-understood. In some species, sex is influenced by environmental conditions, bestowing a reproductive plasticity on these species. Perhaps the most unusual occurs in *Bonellia viridis*, an echiuroid now included within Polychaeta. Here, sex is determined by the settlement of the larva. A larva settling on substrate becomes female, but one settling on an adult female's yard-long proboscis or body wall migrates to the female's uterus, becoming a tiny parasitic male. In this species, material produced by the female has a masculinizing influence on the sex of the larva.

Production of eggs and sperm by specialized organs – ovaries and testes – is most common, but gametes also seem to arise directly from the linings of the coelomic cavity in some species. Ovaries and testes may be permanent or transient (meaning they are not visible when the adults are not in reproductive mode). Gonads may be present in nearly every segment or restricted to part of the body. In *C. teleta*, for example, ovaries are restricted to the first 20–25 abdominal segments. Gametes often mature in the ovaries (*C. teleta*) and testes, in the coelomic cavity (*P. dumerilii*), in other parts of the reproductive tract or in the seawater. Reproductive tracts may be elaborated with species-specific accessory structures, like seminal vesicles in males or seminal receptacles and uteri in females. Gametes reach the external environment via nephridia, specialized gonoducts or coelomoducts, or by rupture of the body wall.

Although males and females are usually separate, in many species hermaphroditism is common (Schroeder and Hermans, 1975). Some serpulids (*Spirorbis* spp.) and hesionids (*Microphthalamis* spp.) develop as simultaneous hermaphrodites, but in others gamete production is sequential. Among species that have been studied, protandry is more common than protogyny. *Ophryotrocha puerilis*, for example, is protandrous, developing first as male, then adopting a female morphology and reproductive mode. In *O. puerilis*, environmental factors (here, the presence of other worms) also play a role in sex determination. Similarly, *C. teleta* males predictably switch to egg-laying mode if the density of conspecifics is low. Whether such hermaphrodites are self-fertile or not is species-specific and often has not been determined.

Asexual Reproduction

Asexual reproduction by budding (seen most often in sessile filter feeders like sabellid and serpulid fanworms), fission or fragmentation is quite common. *Eurythoe* bristleworms, common inhabitants of saltwater tanks, reproduce readily by fragmentation. In many asexually reproducing worms, new anterior (eyes, palps) and posterior (growth zone) structures are well-formed before the individuals separate. Not surprisingly, animals that reproduce asexually are usually able to regenerate missing portions. Superficially, regeneration and asexual reproduction are similar; differences at the cellular/gene level exist and are being explored (Kosyuchenko et al., 2016).

Fertilization

Sexual reproduction involves the fusion of eggs and sperm, so gametes must come into contact. Polychaetes have solved this problem in a number of ways. In species where worms are in close proximity, fertilization is often internal and continues largely independent of environmental factors. Sperm transfer may occur by copulation, hypodermic impregnation or transfer of spermatophores from male to female. Often eggs that are fertilized internally are protected. They may be brooded in specially constructed tubes (*C. teleta*, *Polydora cornuta*), enclosed within the body (the operculum of many spirorbids), placed under the elytra of scale worms, attached to the parent's body (some syllids) or deposited in jelly masses that may or may not be guarded by the parents (*O. puerilis*).

In tube-dwelling polychaetes, broadcast spawning is common with one spawning event triggering other nearby individuals to release their gametes. In many errant polychaetes, massive spawning events are triggered by lunar, tidal and diurnal cycles. Sometimes, even short periods of quite dim light are adequate for synchronization of gametogenesis and spawning (some platynereids). The most famous of these synchronized sexual rendezvous is that of the Palolo worm (eunicids of the South Pacific and elsewhere) that spawn once a year around the seventh night after the full moon that follows the autumnal equinox, and whose gamete-filled bodies are considered a gourmet delicacy.

In preparation for these mating dances, an asexual individual may undergo a dramatic transformation known as epitoky, as breeding season approaches. *Platynereis*, for example, undergoes two types of metamorphic changes – first, from a five-segmented larva to a tubiculous feeding worm, and again when it reaches about 70 segments and begins to make gametes. At that point, it ceases to feed, the gut is resorbed, posterior parapodia change shape, becoming swimming paddles, eyes enlarge, the posterior fills with either eggs or sperm, and worms leave their tubes to become pelagic. Change involves almost every system in the body as an asexual form (the atoke) is transformed into a sexual individual (the epitoke) that is prepared for swimming and mating. Swarming is synchronized by light and the lunar cycle. The mature adults release gametes into the water and die.

In some polychaetes, a budding or splitting of the body occurs. In many nereids and eunicids, for example, the worm becomes divided into an anterior, asexual atoke and a posterior epitoke that produces gametes. At spawning, the epitoke detaches from the atoke and swims to the surface, usually leaving the atoke in the benthos to prepare for another reproductive round. In the Palolo worm (*Eunice viridis*), posterior segments of males and females lose most of their internal organs and become long chains of sperm-filled or egg-filled sacs. At swarming time after the autumnal equinox, these long, headless, strings (epitokes) break off from the parent and swim to the surface where the gametes are released. Spent epitokes drift to the bottom.

Some species use asexual reproduction to bud off entire new gonad-bearing individuals (epitokes), rather than just gamete-filled segments. In these cases, each budded individual develops eyes, palps and other anterior (as well as posterior) features. *Myrianida pachycera* forms a chain of individuals that grow and mature sexually as they are pushed posteriorly (Fig. 1). When gametes are mature, the individual drops off the posterior end.

Early Development

Polychaetes, like molluscs and several other lophotrochozoans, are spiralian. Most undergo typical spiral cleavage. In worms that have been investigated, stereotypical mosaic development is the norm so the fate of blastomeres is predictable. Experiments using *C. teleta* reveal many similarities with other spiralian but also differences, emphasizing the need for further investigations (Seaver, 2014). Like other protostomes, the mouth usually forms from or near the blastopore. The anus is usually terminal.

Fig. 1 *Myrianida pachycera*. Original asexual individual (atoke) budding off epitokes. Picture – Greg Rouse – Tree of Life (*Myrianida pachycera*), Available at: <http://tolweb.org/tolarchive/2486/20020807/Annelida.html>.

Larval Forms and Dispersal

For a reproductive event to be successful, offspring must survive to adulthood and themselves become reproductive. In marine organisms, this often involves a free-swimming, larval stage (Wilson, 1991). Some polychaetes are direct developers (many syllids, some sabellids) with no larval stage. More commonly, however, polychaetes have a swimming larval (dispersal) stage. Often the larva is also a feeding stage, especially if the egg from which it developed was small and non-yolky (Table 1). The classic trochophore – a larval form shared with some other lophotrochozoans (e.g., molluscs) – is a top-shaped free-swimmer that moves through the water propelled by characteristic bands of cilia and usually has a sensory apical tuft of cilia (Fig. 2). Prior to settlement, trochophore larvae undergo initial segmentation, becoming metatrochophores (*Riftia pachyptila*, *P. dumerilii*) or longer, more slender nectochaetes (Fig. 3) that use parapodia for swimming (*P. dumerilii*). Not all larvae go through these stages; *C. teleta*, for example, directly forms a segmented metatrochophore as its only larval stage, bypassing the trochophore and never forming a nectochaete. None are known to metamorphose prior to forming some segments.

Settling and Metamorphosis

For most polychaetes, the larva is an important dispersal stage, enabling the species to colonize new areas often distant from the parents. To accommodate their planktonic life style, larvae may use sense organs quite unlike those of the adult. Eyes (many larvae are phototropic), nuchal organs (putative chemoreceptive organs near the eyes), apical tufts or organs and other sensory cilia are all common. Larvae may remain in the water column, potentially feeding, depending on the species, for several days or weeks, until a suitable area for settlement is found. Even though such larvae are small, approximately 50–200 micrometers in length, their abilities to colonize distant, fragmented and discontinuous sites are remarkable. *Capitella teleta* inhabits disturbed areas of high organic content like the areas under fish farms, polluted harbors and whale falls that may be separated by many kilometers. When larvae in the water column sense suitable substrate, they settle and immediately metamorphose into tiny juvenile worms.

Hydrothermal vents are extremely ephemeral because of volcanic and seismic activities, and yet new vents are colonized quite rapidly even though they may be hundreds of kilometers from old vent sources. The vestimentiferan tubeworm, *Riftia pachyptila*, releases non-feeding trochophore larvae that survive at least 38 days in the water column. The metatrochophore larvae colonize new vent sites tens to hundreds of kilometers away from spawning sites!

Metamorphosis may be undramatic (*C. teleta*) because many adult features are already present, or may involve a major reorganization (*Owenia fusiformis*). At the completion of metamorphosis, young worms usually follow the life style of the adults. Growth, by the addition of new segments at a posterior growth zone in front of the pygidium, usually continues throughout life.

Clitellata

Clitellate annelids are distinguished from other worms by their characteristic reproductive structure, the clitellum, whose function is to secrete an egg capsule, or cocoon. The clitellum appears as a thickened sleeve or saddle a few segments in length within the

Table 1 Diversity of reproductive modes

Reproductive mode	Larval developmental mode	Percentage of > 300 species showing combination
Free-spawning	Planktotrophic	26
Free-spawning	Lecithotrophic	11
Free-spawning	Direct	3
Brooded in tubes	Planktotrophic	10
Brooded in tubes	Lecithotrophic	4
Brooded in tubes	Direct	18
Brooded on exterior of body	Planktotrophic	2
Brooded on exterior of body	Lecithotrophic	2
Brooded on exterior of body	Direct	5
Brooded internally	Planktotrophic	0
Brooded internally	Lecithotrophic	1
Brooded internally	Direct	6
Encapsulated in gelatinous mass	Planktotrophic	3
Encapsulated in gelatinous mass	Lecithotrophic	5
Encapsulated in gelatinous mass	Direct	4

Note: Table combines reproductive methods and type of larval development (feeding) modes. Planktotrophic – larvae feed on plankton; lecithotrophic – larvae are non-feeding and are provisioned with nutrients by yolky egg; direct – young develop directly as miniature adults with no larval form or metamorphosis.

Source: Modified from Wilson (1991. Sexual reproductive modes in polychaetes: Classification and diversity. Bulletin of Marine Science 48, 500–561). The journal is published by the Rosenstiel School of Marine & Atmospheric Science, University of Miami, 4600 Rickenbacker Causeway, Miami, FL 33149-1031, United States and based on characteristics of over 300 polychaete species belonging to 36 families illustrating diversity of reproductive modes.

anterior third region of the worm. During periods of sexual maturity, it swells with thousands of glands that secrete proteinaceous material for building the cocoon (Coleman and Shain 2009; Rossi *et al.*, 2013).

Clitellates are hermaphrodites (i.e., individuals containing both male and female reproductive structures) and both male and female gonopores exit from the clitellum. Like polychaetes, most clitellates reproduce sexually but some proliferate rapidly by asexual fragmentation or budding, while others (e.g., Naididae) can alternate between sexual and asexual modes of reproduction depending upon environmental conditions (Parish, 1981).

Sexual Reproduction

Though some clitellates are capable of self-fertilization (e.g., *Tubifex tubifex*) or parthenogenesis, most cross fertilize by copulation. This involves physical contact between two individuals and the mutual exchange of sperm, usually via an intromittent organ or by the transfer of a sperm-filled sac called a spermatophore. Spermatophores are cemented to each other in the prostate bulb and transferred to the ventral body surface of the partner, typically in the clitellar region. Sperm exit the spermatophore, and by a mechanism not fully understood find their way via the coelomic sinuses to ovaries, where the eggs are fertilized internally.

Spermatogenesis occurs in paired testisacs and resulting spermatozoa pass through structures including the vas deferens and atrium before longer term storage in the epididymis (Fig. 4). Paired ovisacs give rise to oogonia and oocytes, which pass through oviducts that converge and lead to the female pore. Eggs may acquire yolk by a process called vitellogenesis and can be quite large (up to several mm in some Glossiphoniids), or yolk may be deposited into cocoon fluid as a nutritional source for developing embryos (albumenotrophy). Sperm from a partner may be stored in specialized compartments called spermathecae, and released during egg laying to fertilize eggs internally or in the cocoon.

Asexual Reproduction

Many clitellates, excluding leeches, can undergo asexual reproduction by fragmentation, paratomic division (forming a chain of zooids), or parthenogenesis. For naidids, fragmentation is the dominant form of reproduction and enables them to rapidly populate an environment under favorable conditions (Parish, 1981). Fragmenting worms are also a model system for studying regeneration (e.g., *Lumbricus variegatus*), since both anterior and posterior ends can fully regenerate from as little as two midbody segments!

Cocoon Production

In coordination with egg laying, clitellates secrete a proteinaceous cocoon that provides a microenvironment for embryonic development (Coleman and Shain, 2009). The process initiates by the proliferation of clitellum-specific granular cells that differentiate into two cell types, one of which makes fibrous protein that builds the cocoon wall and another that secretes a glue-like substance to seal the cocoon ends. Several million granules of each material type (i.e., cocoon wall, glue) are necessary to construct a single cocoon. Secreted wall granules initially self-assemble to form a sheath around the clitellum. Upon the release of eggs and cocoon fluid from the female pore into the sheath, the worm pulls its head through while simultaneously sealing both ends of the sheath with granulated structures called opercula (Sawyer, 1986). In some leeches (e.g., *Helobdella*), the cocoon is secreted from a ring of granular cells surrounding the female pore and forms a sac that is sealed with a single operculum. Typically only a few cocoons are secreted over the course of several hours, but up to ~50 have been reported in some worms (e.g., *Myzobdella lugubris*). The number of eggs deposited into each cocoon ranges from one to more than 100, depending on the species.

Fig. 4 Dorsal view of a clitellate (*Helobdella* sp.) reproductive system (A) Position of reproductive system in body. (B) Dorsal dissection. (C) Schematic reproductive organs. a, atrium; ac, atrial cornua; os, ovisac; od, oviduct; sd, sperm duct; t, testis; vd, deferens.

Fig. 5 Morphology of representative clitellate cocoons. (A) *Erpobdella punctata*. (B) *Theromyzon tessulatum* (C) *Tubifex tubifex*, with juvenile exiting. (D) *Eisenia fetida*. Arrows identify opercula. Scale bar=100 μ m.

Clitellate cocoons display a variety of morphologies (Fig. 5) but fall into three general categories: hard-shelled, membranous and gelatinous (Siddall and Bureson, 1996). These are distinguished mostly by the thickness of the fibrous cocoon wall. In some terrestrial taxa (e.g., *Hirudo*, *Haemopsis*), a spongy matrix surrounds the cocoon and appears to prevent desiccation by trapping water droplets. The components of clitellate cocoons display extraordinary physiochemical properties (e.g., thermal, chemical resilience), making them valuable resources as biomaterials and bioadhesives.

Parental Care

Annelids tend to show parental care of some form, ranging from brooding embryos in tubes to placing them in cocoons. Glossiphoniid leeches (e.g., *Haementeria*, *Helobdella*, *Theromyzon*) brood their cocoons until embryos hatch, at which time up to several hundred juveniles may attach to the venter of the parent. Throughout the care period, the parent provides protection from predators and ventilates the eggs/young to ensure that they receive sufficient oxygen. In the sanguivorous duck leech, *Theromyzon*, the parent brings juveniles to their first blood meal, a duck nose, before terminating its life cycle.

Some fish leeches (e.g., Piscicolidae) exhibit an adaptation that facilitates an early blood meal. Rather than abandoning their cocoons as most oligochaetes do, they instead cement them to the surface of crustaceans, which are later eaten by fishes. When the young leeches hatch, they readily attach to the fish host's buccal surfaces and migrate to the gills. In some Syllidae oligochaetes, eggs are not released but rather attach to the posterior end of the worm where they develop into juveniles before becoming independent.

Glossary

Asteroids The echinoderm taxon consisting of sea stars.

Autonomy A common feature of sea stars and brittle stars in which the adult severs an arm, often to escape a predator.

Bilateral symmetry Symmetry along a midline of an organism. Both sides divided by the midline are roughly similar in morphology. For example, in a human, a line drawn from the forehead to the chin, going through the nose, separates a left and right side to the head, which superficially is the same.

Egg A female gamete capable of being fertilized. Different in development from an oocyte, which is not fertilization competent.

Gene regulatory network A mechanistic examination of how genes regulate expression of each other through their activation and repressive functions in transcription.

Gametes Eggs and sperm, the cells of sexual reproduction.

Germ line The lineage of cells from gametes to embryos, to gametic stem cells in the gonad that carries the genetic information used by an animal in sexual reproduction.

Meiosis The reduction division transforming the gametes from 4 copies of each chromosome, to one copy (haploid). Upon fertilization then, the number of copies of chromosomes is restored to two copies (diploid) by merger of haploid sperm genome with haploid egg genome.

Mutable connective tissue (MCT) Extracellular matrix that responds directly to nerve signals to change its structure, and thereby initiate movements within a section of the animal.

Oocyte A cell developing into an egg. The difference between the two is not in meiosis, or timing of fertilization but in a functional definition. It is whether the cell is capable of being fertilized (egg) or not (oocyte).

Pedicellariae Food catching appendages in the adult of many echinoderms, especially prevalent in sea urchins.

Pentameric symmetry Five-fold radial symmetry characteristic of adult body plan of echinoderms.

Tube feet Suction-cup like movable apparatus on echinoderm adults to attach to objects and/or pass food to the mouth. These devices are powered by the water vascular system.

Zygote Fertilized egg until the cell divides, when it is then referred to as an embryo.

Introduction

The image of echinoderms is prevalent in society. From sea star enhanced signs on restaurants to sand dollar key chains, most people have an inherent connection to echinoderms. Many people may not know though that they are a favorite of many for studying mechanisms of reproduction and development, and are more closely related to ourselves than all other invertebrates. Echinoderms represent an early branching phylum of deuterostomes, an evolutionary branch that resulted in vertebrates, with over 7000 living species identified worldwide. Echinoderms also have a rich fossil record enabling examination of speciation and evolutionary diversification of morphology. For general interest in reproduction, in development, in ecology and evolutionary biology, and in marine biology, echinoderms are an important group of animals to understand.

What Are Echinoderms?

The phylum Echinodermata is comprised of five taxa (classes) of organisms with overlapping, yet diverse, characteristics. The shared characters include radial symmetry – usually five-fold symmetry – in the adults as well as a body wall skeleton, a water vascular system used for motility in tube feet and food catching devices (pedicellariae), and mutable connective tissue (MCT). This latter character may be unique to echinoderms in that the extracellular matrix undergoes significant structural changes without the use of muscles. This character for many echinoderms likely participates in the process of mouth movement, and autonomy, a common feature of sea stars and brittle stars in which the adult severs an arm to escape a predator. In this process the MCT is likely stimulated to become highly flaccid and rupture by the tension of the arm.

The Five Classes of Echinoderms

Fig. 1 highlights the diverse groups of echinoderms (Cary and Hinman, 2017). Perhaps the most recognizable member of echinoderms are the sea stars (Asteroidea; historically many have called these animals starfish but because they are not fish, marine

biologists have preferred the term sea star to minimize any ambiguity of its taxonomic position, and for consistency with sea urchin, sea cucumber, etc.). These animals usually have five distinct arms, each connected to a central body disk that contains the mouth and integrated nervous system. Each of the arms has its own gonad (in the adult), nerve system, and digestive organ connected to the central digestive system. The mouth is on the bottom (ventral, oral surface) surface of the animal, the anal and five (pentaradial)

gonadal openings on the top (dorsal, aboral surface). Many sea stars (e.g. *Asterias*) are highly predatory and consume large numbers of animals even slower than they are e.g. molluscs. The main strategy in mollusk consumption for a sea star is to use their tube feet to attach to the shells of the mollusks and to apply separating tension over a long period of time. The slow movement muscles and water vascular system of the sea star eventually exhaust the mollusk, who eventually begins to open its shell. The sea star then everts its central digestive system through its mouth into the opening of the mollusk, and releases digestive enzymes to begin consuming and eventually overcoming the remaining mollusk tension. Other sea stars are capable of consuming benthic detritus for sustainability.

Similar in shape and design to the sea stars are brittle stars of the taxon, *Ophiuridea*. These animals have a distinct central disk with long slender arms emanating from five distinct sites. The movement is somewhat spider like, and their arms are densely packed with tube feet and graspers to capture and passage food to the mouth. The digestive system is much simpler than the sea star, with a stomach sack with openings in the mouth for intake and outflow. The gonads are located in the central disk with gonadopores equally spaced around the disk. A sub-group of *Ophiuridea* consist of the basket stars, containing highly elaborate branching arms that make the animal arms look more fern-like. These brittle star relatives are highly predatory in that they capture suspension zooplankton and pass the food along their convoluted arms to their mouth.

One of the more unusual groups of echinoderms are the sea cucumbers, *Holothuroidea*. As their common name implies, many of this group look remarkably like the cucumber vegetable, or pickles of the sea. These animals look very different than the pentaradially symmetric sea star and brittle star, with a strong anterior-posterior organization, dense and branched tentacles surrounding the mouth, a single gonad within the body, and a calcareous skeleton ring surrounding the mouth. The tentacles scoop sediment and debris into the oral opening, to be digested by a robust stomach system leading out of the animal in the posterior anal opening. When threatened, many of these animals will evert and autonomize their gut, but eventually regenerate this entire digestive structure.

Crinoidea (feather stars, sea lilies) are distinctive and unusual echinoderms. Highly arborized arms are joined on a central disk, or even long stalk that serves as a mechanism to be off the sea floor and maximize their filter feeding capabilities. The extensive arms on the stalked crinoids are capable of selecting suspension materials that they will then pass to the mouth. The digestive system leads to an anal opening near or on the stalk. Crinoids are thought to represent an early branching echinoderm and may represent an important and ancient diversification between protostomes (development in which the mouth is formed first and by the blastopore) and deuterostomes, in which the initial opening at gastrulation becomes the anal opening. Little is known about how these animals develop and function, but because of their highly calcified stalk system, the fossil record of these animals is rich.

Perhaps the best studied of echinoderms are the *Echinoidea*, the sea urchins and sand dollars. Their calcium carbonate test enables a dense fossil record, their prevalence in coastal areas and shallow-water marine environments has tremendous impact on the ecology of a system, and the many eggs spawned by the adults enable rapid and deep research into mechanisms as wide ranging as nutrient storage, fertilization and embryogenesis, cell shape changes and cell cycle regulation, gene regulatory networks, and ecotoxicology. The adults have characteristic spines that may extend only a few millimeters to many centimeters from the body wall. In some species these spines are thick and blunt as in the pencil urchins (*Eucidaris*), whereas in other species, the long spines are barbed like a fish hook and difficult to remove without further damage if the spines penetrates your skin (e.g. *Diadema*). The adult coelom is lined by five symmetric gonads and an asymmetric digestive system that loops around the body wall. The mouth has a distinct set of five teeth in the shape of Aristotle's lantern, leading to the digestive system, and the anal opening (on top, or the aboral surface) is surrounded by five openings, the gonadopores, through which eggs and sperm are released from each of the gonads.

Reproduction and Development

Overview of Reproduction in Echinoderms

As diverse as this phylum is in morphology, so too it is diverse in its reproduction. Most echinoderms reproduce sexually, making eggs and sperm, but some species also reproduce asexually, by splitting the adult body and regenerating the divided pieces. In some species, the larvae also reproduce by splitting off parts of the larval body in a process called larval cloning. Some adults are hermaphrodites (adults make both testis for sperm, and ovaries for eggs) whereas most species are single sexed. The vast majority of reproduction in echinoderms is by broadcast spawning, releasing eggs and sperm into the water column and favoring the strategy of making large numbers of eggs and sperm (Fig. 2), with the result that only a small percent of the gametes released will actually be successfully fertilized and develop. Yet an even smaller number will successful survive the time needed for development to another gravid adult. Yet in the generation of millions of eggs and trillions of sperm over an adult lifetime, growing a population of sea urchins is quite successful given appropriate nutrition.

Sexual Reproduction in Echinoderms

The reproductive anatomy of echinoderms generally follows their radial, usually five-fold, symmetry (Fig. 2). Adults of sea stars and sea urchins for example, have 5 openings on their aboral (the side opposite the mouth, or oral opening) through which are released the eggs or sperm. These pores of the gonad (gonadopores) are connected to each lobe of the gonad inside the body of the adult. Generally the structure of each gonad follows the same orientation for males and females (Fig. 3). The precursors of eggs and sperm

Fig. 2 (A) Spawning sea urchin (*Strongylocentrotus purpuratus*; native to the west coast of the United States), seen from the dorsal (aboral) surface of the adult. (B) When the animal is opened on the ventral aspect, the pentameric (five-fold) symmetry is obvious in the gonads – here a female with the yellowish, yolk laden ovaries seen prominently, each containing upwards of a million eggs. Photo courtesy of Jacqueline Brooks. (C) Female (left) and male (right) spawning in sea water and “dry” respectively. Fertilization is then accomplished by mixing the gametes in sea water. (oocytes, and spermatocytes, respectively) develop from stem cells along the periphery of the branched tubular structure (Fig. 3). Gametogenesis is apparently independent of age of the animal such that once juveniles reach a certain age/size, they are capable of making eggs or sperm for the rest of their life. Given that some species of echinoderms have been clocked at living over 200 years, we conclude that the reproductive stem cells are continually replicating and functional.

Most echinoderms are seasonal. That is, they make eggs and sperm only during parts of the year (Fig. 4). This cyclicity in gravidity is regulated by a variety of environmental conditions including nutrition, temperature, and light, and will fluctuate from gonads packed full of gametes to gonads only a shadow of their prime, with no detectable eggs or sperm present (Perez *et al.*, 2010). What happens to their stem cells in the gonad and why do they not make more sperm and eggs? This is not clear, but some reports suggest, at least in a sea star, that the stem cells accumulate in a specialized region of the body wall, near the gonadopore openings, and stop dividing. Presumably they re-ignite to replicate and make more precursors in the development of eggs and sperm following their migration, or re-proliferation to the branched tubular gonads. Recent research in germ line formation and function in a variety of animals suggests that at least some echinoderms may make germ line stem cells (the stem population of cells that give rise to eggs and/or sperm) in a variety of different developmental pathways, perhaps even using transitions in somatic (normal body) cells to make germ cells, dimming the normal divide of germ line and soma from classical studies.

Fig. 3 Gonad structure and function. (A) In situ RNA hybridization of an mRNA for cortical granule contents (blue signal within a whole mount of a sea urchin ovary) showing the distribution peripherally of developing oocytes of many stages. (B) Diagrammatic representation of oocytes, eggs, and follicle (somatic) cells of a sea urchin ovary.

Fig. 4 Cyclic behavior of seasonal fecundity in a sea urchin. Photomicrographs of both testis and ovary are shown throughout a year, and graphically displayed showing how the gonad size varies with photoperiod and water temperature. Testis stages of *L. albus*: (a) immature, (b) growing, (c) premature I, (d) premature II, (e) mature, (f) spawned. Scale bar 50 m. Ovary: Photomicrographs of females gonadal stages of *L. albus*: (a) immature, (b) growing, (c) premature I, (d) premature II, (e) mature: free oocytes in the alveolar lumen, (f) spawned: immature oocytes attached to the alveolar wall and few free oocytes in the lumen. Scale bar 50 m. Great variation is seen in how animals respond to environmental conditions with both proportional and inversely proportional responses to light and temperature. Reproduced from Perez, A.F., *et al.*, 2010. Reproductive cycle and reproductive output of the sea urchin *Loxechinus albus* (Echinodermata: Echinoidea) from Beagle Channel, Tierra del Fuego, Argentina. *Polar Biol* 33 (3), 271–280.

Many investigators use echinoderms to study mechanisms of sperm-egg interaction, fertilization, and activation of development because of the many gametes available for study, that they can be fertilized outside of the adult and visualized under the microscope, and because they can be manipulated by microinjection of materials for experimentation. These are each valuable resources for scientists and educators alike. These investigators will stimulate the animal by gently shaking the adult, and/or by injection of KCl into the body cavity of the adult, stimulating contraction of the smooth muscles that surround the gonads causing expulsion of the gametes stored in each of the gonadal lumens out through the gonadopores (see especially sea star, Fig. 2). The mechanisms used normally by adults in the wild though are not at all understood.

A variety of mechanisms appear able to induce spawning in adult echinoderms. Stress from shaking (wild wave action), or rapid changes in environmental conditions (temperature, salinity, oxygenation) often induce the animals to spawn when gravid. Some species actually respond to the lunar cycle. For example, the sea urchin *Diadema* undergoes regular spawning at the full moon. Whether this is due to light from the moon (unlikely, since they still do so even with cloud cover or rain) or tidal conditions (more likely, but not clear how this would work since they may be many meters below the ocean surface), is not clear. Once induced to spawn though, they often release the vast majority of their gametes, and over the next 28 days of the lunar cycle, will synchronously develop a new cohort of eggs or sperm in time for the next full moon.

An adult echinoderm of one species that begins to spawn will induce nearby adults of the same species to also spawn. This leads to a large spawning event in the wild that brings eggs and sperm together at the same time and space, thereby increasing the chances that fertilization will occur. Some species can also induce spawning in other, closely related species.

Fig. 5 Oogenesis and meiosis. These samples were shed and dissected an ovary of the sea urchin *L. variegatus* and viewed with a light microscope. (A) Oocytes attached to the somatic cells of the ovary. (B) Previtellogenic primary oocytes. (C–E) Vitellogenic growth phase of oogenesis. (E–I) Full-grown oocytes complete meiosis with the large germinal vesicle moving asymmetrically to the cell periphery, where it breaks down and extrudes two polar bodies to produce a haploid mature egg that is now ready for fertilization. Scale bar, 50 μ m; gv, germinal vesicle; nc, nucleolus; pbs, polar bodies; pn, pronucleus. Figure adapted from Brooks, J.M., Wessel, G.M., 2003. Selective transport and packaging of the major yolk protein in the sea urchin. *Dev Biol* 261 (2), 353-370, with permission.

Meiosis

Most eggs made by animals, including most echinoderms, are spawned and fertilized at some point during meiosis, the reduction division transformation the gametes from 4 copies of each chromosome, to one copy (haploid). Upon fertilization then, the number of copies of chromosomes is restored to two copies (diploid). Sea stars for example, store millions of oocytes in a germinal vesicle stage. Upon spawning, the follicle cells surrounding the oocyte release 1-methyladenine, which initiates resumption of meiosis. Fertilization can then be successful – prior to this, depending on the species, sperm may not bind, or the oocyte is incapable of blocking more than one sperm from entering the egg (block to polyspermy). Although the details differ from species to species, many other animals, including humans, have analogous events in the meiotic mechanisms and in fertilization. Thus, the many millions of oocytes stored by a sea star (see Figs. 2 and 5) enables more tractable study to the meiotic events in oocytes. Unusual in eggs of Echinoidea is that the eggs are released having completed meiosis. Thus, once the sperm fuses to the egg, two haploid cells are fusing to restore diploidy, independent of completion of meiotic processes. The only other eggs known that complete meiosis prior to fertilization are some cnidarian.

Fertilization Mechanisms in Echinoderms

The eggs and oocytes of echinoderms are wonderfully suited for observation of, and research into, meiosis (see above) and fertilization. Large numbers of eggs are readily observable and manipulatable in simple culture systems making them efficient for study. Further, many of the mechanisms of fertilization and activation of sperm and egg are highly conserved, even though the molecular details, or the molecules themselves, are diverse. A few of the more conserved features of fertilization include:

1. Eggs have an extracellular layer that activates sperm by a species specific mechanism. In sea urchins, this layer is the egg jelly that consists of sugar polymers and small peptides.
2. Activated sperm (acrosome reaction and metabolic increase) are able to penetrate the egg extracellular layer and bind to the egg species specifically.

3. Egg activation results in steps to block additional sperm from binding and fusing to the egg. This process is called the block to polyspermy.
4. Echinoderms and many other species have two mechanisms to block polyspermy, a) a change in the electrical potential of the plasma membrane which is rapid, but transient, and b) a slower, but permanent change in the egg extracellular matrix.
5. The slow block to polyspermy uses contents of the cortical granules, secretory vesicles in the periphery of the egg, to reconfigure the extracellular matrix into an impenetrable barrier to sperm. The embryo must subsequently hatch out of this encasement in order to feed (sea urchins) or implant (mammals).
6. Signal transduction pathways initiated by sperm fusion to the egg causes release of calcium from intracellular stores (endoplasmic reticulum) in the egg to stimulate secretion of the cortical granules and for activation of programs to initiate development of the embryo.

The abundance of eggs and sperm in echinoderms and their functionality in vitro has enabled a robust identification of many of the key features in egg activation. Some of these steps and the molecular players involved are diagrammed in Fig. 6. See also the

Fig. 6 Milestones of fertilization envelope formation. Diagram detailing the time-course of modification of the egg cortex and fertilization envelope assembly, starting from sperm fusion (top) to ovoperoxidase-dependent crosslinking (bottom). Milestones are highlighted, and are described in the text. In panel (7), arrows denote dityrosine crosslinks formed by active ovoperoxidase. CGSP1, cortical granule serine protease 1 (proCGSP1=zymogenic form); H₂O₂, hydrogen peroxide; OVOP, ovoperoxidase (ovop=zymogenic form); PLN, proteolisin; RDZ, rendezvin; "R-Y5Y-R", covalent dityrosine crosslink; "R-Q=K-R", covalent epsilon(gamma-glutamyl)lysine bonds; TG, transglutaminase; Udx1, urchin dual oxidase 1; 40 kDa, macromolecules of 40,000 daltons. Fig. 7 Development in a sea urchin. Left, diagram of the development of a sea urchin. Early development yields Vasa-positive cells (shown in red, beginning with a uniform Vasa positive egg and early embryo). At the 32-cell stage, the sMics are uniquely Vasa-positive. These cells move into the coelom during gastrulation, segregate into the left and right coelomic pouches, and expand to contribute to the germ cells of the adult, and likely also to some somatic cells of the rudiment (Reproduced from Wessel, G.M., *et al.*, 2014. The biology of the germ line in echinoderms. *Mol Reprod Dev* 81 (8) 679–711.). On the right is a montage of key developmental transitions in the sea urchin *Lytechinus variegatus* (reproduced from Etensohn, C.A., Wessel, G.M., Wray, G.A., 2004. The invertebrate deuterostomes: An introduction to their phylogeny, reproduction, development, and genomics. *Methods Cell Biol* 74, 1–13, with permission). (A) fertilized egg with prominent fertilization envelope surrounding the cell; (B) two – cell stage; (C) four cells; (D) 16 cell stage showing the unequal cleavage at the bottom yielding 4 macromeres, and 4 micromeres; (E) morula; (F), Blastula; (G) late blastula becoming asymmetric from top (animal) to bottom (vegetal poles); (H) primary mesenchyme cell stage with invaginating primary mesenchyme cells; (I) early gastrula with invaginating endoderm; (J) mid-gastrula; (K) late gastrula in which the invaginating endoderm has reached the opposite pole to form the future mouth. The future anus is at the bottom, the site of invagination. (L) different focal plane of same embryo showing the primary mesenchymal cells. (M) prism stage – early larva. (N) larva with arms and skeleton extending. (O) larva with extensive growth in arms. For scale the egg is approximately 100 μm in diameter.

VirtualUrchin (see Relevant Websites section) as to how to visualize fertilization, adjust the microscope, and even ship adults and/or eggs and sperm for classroom or research utility. Echinoderm eggs and sperm are viable for several days out of the adults, and prior to fertilization, so shipping these cells is feasible for many applications.

Can eggs and sperm from different species cross fertilize? Generally not. Under experimental conditions, cross fertilization (hybridization) can occur, but success in the development of the embryos is usually low, and few, if any, reports of interspecies echinoderm adults propagating are known and validated.

What is the reason for eggs and sperm from different species not fertilizing each other? Both sperm and eggs have several mechanisms whereby molecular specificity is required for gamete interaction and successful activation of development. This starts with the jelly surrounding the egg that activates sperm in a species specific manner, to the rapid evolution in sperm and egg binding proteins on each gamete. This molecular lock and key between sperm and egg of the same species is just one mechanism required for a successful fertilization within the same species.

Embryonic Development

Development of echinoderm embryos is easy to observe (Etensohn *et al.*, 2004; Fig. 7) because the embryos normally develop outside of the adults in natural sea water. This condition is easily replicated in the lab or classroom and their size is amenable to manipulation without demands for advanced microscopy equipment.

Fertilization is readily apparent by formation of the fertilization envelop. The first few cell divisions are equal, the speed of which depends on the temperature and the species, but can be every 30 min to every few hours. For most echinoderm the cell divisions

continue equally, at least in size, but in sea urchins, the next two divisions have an asymmetric division. By definition the site of the egg where meiosis occurred is the animal pole, and the side opposite it is the vegetal pole. The small cells formed (micromeres) at the vegetal pole of the embryo of the fourth and fifth cell divisions have important differences in cell fate. One of the small cells becomes strictly limited to making skeleton in the larva, whereas the other cell (the smaller quartet of the two) contributes to the germ line, that lineage resulting in sperm or eggs in the adult. A blastocoel soon forms in the middle of the dividing cells and expands to form the blastocoel, a cell free space filled with extracellular matrix molecules. The embryo is now a single layered epithelium undergoing rapid cell divisions. Three primary germ layers form during gastrulation, the process of converting the hollow – balled blastula into a three layered structure; ectoderm (nerve cells and “skin cells” on the outside), endoderm (digestive tract in the inside) and mesoderm (muscle, immune cells, skeleton in between). These now distinct germ layers continue replicating their cells and become diverse in their structure and function. Once the mouth forms by fusion of the invaginating endoderm with the overlying ectoderm, the animal can begin feeding. In general, all indirect developing (see below) echinoderms have similar morphogenesis to this point. Eating is then associated with growth of the larva, which funnels food by elaborate cilia into the digestive track. The larvae become diverse and complex in their structure and function. Excellent coverage of these topics are found in e.g. [Byrne and O’Hara \(2017\)](#), [Giese et al. \(1991\)](#), [Smith \(1997\)](#) and from Relevant Websites section.

Direct Versus Indirect Development

Most of the embryos that develop in each of these taxa are indirect developers, that is, they develop into a motile, and bilaterally symmetric larva first that eventually metamorphoses into a juvenile. The subsequent adult stage will ultimately make eggs and sperm again to complete the cycle. There are, however, in each of the groups within the phylum, extreme variations in this strategy. Many species of echinoderms instead develop directly into an adult, without passing through a larval stage. These so call direct developers often have very distinct eggs laden with large amounts of yolk, oil droplets, and fatty acids to supply the developing embryo with the nutrition necessary to obviate a feeding larval stage until the juvenile is capable of feeding. In some cases these eggs have so much oil reserves that the eggs are buoyant. A great deal of research is invested in understanding the evolutionary transitions that may have occurred between indirect developers, likely the ancient strategy of development in echinoderm, and direct developers, a derived developmental fate in this phylum. For more detailed information and for more methodology on studying these major life history changes, see [Zigler and Raff \(2013\)](#) and [Israel et al. \(2016\)](#).

Fossil evidence suggests that the early echinoderms were bilaterally symmetric, and likely evolved from bilaterally symmetric precursors. The early evolving phylum then underwent a radical change in body structure within the adult, likely during metamorphosis within the rudiment of the adult developed by the larva. How this occurred is not known, but is of great interest in evolutionary developmental morphology. See [Zamora et al. \(2012\)](#) for details of the research leading to this conclusion.

Cell Cycle and Developmental Synchrony

Some echinoderms release millions of eggs and upon fertilization, will usually develop synchronously into larvae. Especially the early cell divisions are quite uniform in these animals, and this property enables a large diversity of research into developmental mechanisms since many embryos can be visualized at once, and molecular mechanisms can be tested more readily with the abundance of samples. This is very different to many other animals, especially e.g., humans, which release on average one egg every 28 days, and round worms (*C. elegans*), which make on average ~200 eggs. This property of echinoderms was leveraged to examine the cyclicity of specific protein synthesis and degradation, leading to the identification of the cell cycle regulators, the cyclins ([Evans et al., 1983](#)).

Gene Regulatory Network

Development of an embryo is a process of regulating gene expression in specific times and places. How genes are expressed, and then how they influence the expression of other genes, is referred to as the gene regulatory network. Echinoderms are an important model system in unraveling how this network functions, and how it evolves. By comparing closely related groups of echinoderms e.g. sea stars, sea urchins, one can begin to understand how interactions of certain groups of genes may change with time, or be retained unchanged to function in various processes. These investigators will document their findings by use of a “wiring diagram”-like graphic to indicate interactions between genes that are positive (activate transcription), or negative (repress transcription). See [Fig. 8](#) for an example from a sea urchin and the following references for more details on how the gene regulatory network is studied ([Cary and Hinman, 2017](#); [Hinman and Cary, 2017](#); [Hinman and Jarvela, 2014](#); [Peter and Davidson, 2015, 2016, 2017](#)).

Formation of the Germ Line in Development

The reproductive system and strategy of an organism is the most important mechanism for propagation and survival of the species. Within these mechanisms are the somatic components of the reproductive system and the germ line cells. Both of these lineages are essential for reproduction. The somatic cells are those cells that support the development, passage, and products of the germ line cells. These cells and tissues are not passed on to subsequent generations, but are essential for reproduction. The reproductive system is enormously diverse between various organisms, and depends on the reproductive niche of the organism. The germ line is that

Fig. 8 Shown is a “wiring diagram” for gene regulatory networks in a region in the embryo of the sea urchin *Strongylocentrotus purpuratus*. Arrows indicate activation steps in the program whereas bars indicate repressive activities. Reproduced from Davidson Lab Gene Regulatory Networks. Available at: <http://www.spbase.org/endomes/>.

lineage which is committed to give rise to the gametes of the organisms, the sperm and eggs. The genome of these cells is potentially immortal in that they pass on their nuclei from generation to generation through the fertilization process. These cells too are enormously diverse and respond to, or modify the reproductive strategy, through which the organism is selected (Figs. 9 and 10).

How Do Animals Make a New Germ Line?

Two extremes are considered in understanding this process, though organisms are clearly graded in these mechanisms. One mechanism, originally found in the fly *Drosophila* and used by sea urchins, is to have molecular information stored in a specific region of the egg. As the embryo develops, cells that acquire the region with stored germ line information are directed to develop into the germ line of the organism. Many of the organisms used in laboratory research, such as zebrafish, the clawed toad, *Xenopus*, the round worm *C. elegans*, and the fly *Drosophila*, use this mechanism in germ line formation. Mammals instead use a distinct mechanism for germ line formation, and rely on cell–cell interactions to direct cell fate in the future germ line. This so called inductive mechanism appears to be the ancient, original, mechanism of how organisms selected their germ line cells, and many different species throughout phylogeny have evolved the derived strategy of germ factor acquisition instead. Embryos of sea stars, brittle stars, and sea cucumbers appear to have retain the ancient program of inductive germ line acquisition whereas sea urchins and sand dollars are thought to be the only taxon to have diverged from this strategy (Wessel *et al.*, 2014a,b).

Once the germ line is formed in the sea urchin, or in the sea star, the same group of molecules appear to be important in order for the germ line to become fated for the germ line, migrate to the somatic gonad, propagate into germ line stem cells, and eventually form functional gametes of eggs or sperm. These germ line factors are usually found in all organisms with a germ line, though it is becoming apparent that they are not expressed exclusively in the germ line. Many of these factors are now found in somatic cells, are over expressed in regenerative tissues, in cancers, and even in the nervous system.

Sea urchin orthologs identified that are generally involved in specifying the germ line in organisms widely throughout phylogeny are shown in Table 1, and the germ line cells in a sea urchin are shown in Fig. 7.

Brooding in Echinoderm Reproduction

Some echinoderm species have brooding pouches into which fertilized eggs are deposited. The embryos develop within these protected areas and only upon reaching more advanced stages are they released to populate the water column. While not the equivalent of a marsupial pouch, the pouch provides protection and may even supply nutrients to enhance the development of the young.

Table 1 Listing of orthologs of germ line factors found in the sea urchin *S. purpuratus*

Gene	Genbank accession	Domains and function	Orthologs (BLAST score ^a)
<i>Sp-boule</i>	XP786845	RNA recognition motif (RRM) and DAZ repeats, translational regulator involved in germ cell development and meiosis	<i>S. oedipus</i> (1e–29) <i>H. sapiens</i> (4e–29)
<i>Sp-CPEB1</i>	XP786947	2 RRM domains, translational regulator during oogenesis (Chang <i>et al.</i> , 1999; Gebauer and Richter, 1996; Hake and Richter, 1994)	<i>M. glacialis</i> (2e–163) <i>H. sapiens</i> (1e–128)
<i>Sp-germ cell-less</i>	XP793954 XP784533	BTB (Broad-Complex, Tramtrack and Bric a brac) protein interaction domain, conserved nuclear pore-associated protein required for germ cell formation in <i>Drosophila</i> (Leatherman <i>et al.</i> , 2000)	<i>M. musculus</i> (5e–113) <i>D. rerio</i> (1e–112)
<i>Sp-DMRT</i>	XP790843	Doublesex DNA-binding motif (DM), transcription factor involved in sex determination	<i>P. troglodytes</i> (7e–33) <i>H. sapiens</i> (7e–32)
<i>Sp-mago nashi</i>	XP791004	No defined domains, required for localization of oskar mRNA in <i>Drosophila</i> germ plasm assembly (Newmark and Boswell, 1994)	<i>X. laevis</i> (6e–72) <i>H. sapiens</i> (8e–72)
<i>Sp-MORC</i>	XP790047	2 coiled-coil domains, nuclear protein required for spermatogenesis in mouse (Inoue <i>et al.</i> , 1999; Watson <i>et al.</i> , 1998)	<i>R. norvegicus</i> (1e–126) <i>M. musculus</i> (1e–126)
<i>Sp-MSY</i>	XP785816	CSP or Y-box binding domain, translational repressor during mouse spermatogenesis (Giorgini <i>et al.</i> , 2002)	<i>M. musculus</i> (6e–30) <i>H. sapiens</i> (1e–29)
<i>Sp-nanos2</i>	ABB89047	CCHC Zinc Fingers (2), translational regulator (with pumilio), conserved role in germ cell development	<i>N. vectensis</i> (7e–21) <i>H. sapiens</i> (2e–17)
<i>Sp-ovo</i>	XP788176	C2H2 Zinc Finger (4) transcription factor, plays a role in <i>Drosophila</i> oogenesis and mouse spermatogenesis (Dai <i>et al.</i> , 1998; Mével-Ninio <i>et al.</i> , 1991)	<i>H. sapiens</i> (6e–52) <i>D. melanogaster</i> (7e–52)
<i>Sp-pumilio</i>	XP794621	Pumilio-like repeats (3), translational regulator (with nanos), conserved role in germ cell development	<i>X. laevis</i> (0) <i>T. nigroviridis</i> (0)
<i>Sp-seawi</i>	AAG42534	PAZ (piwi, argonaute, zwiille) domain, required for maintenance of germ line stem cells	<i>H. sapiens</i> (0) <i>M. musculus</i> (0)
<i>Sp-SoxE</i>	XP786809	HMG box transcription factor involved in sex determination	<i>P. lividus</i> (0) <i>X. tropicalis</i> (3e–45)
<i>Sp-tudor</i>	XP780689	Tudor domains (5), required for <i>Drosophila</i> pole plasm assembly and is expressed in mouse spermatocytes (Chuma <i>et al.</i> , 2003; Thomson and Lasko, 2004)	<i>H. sapiens</i> (4e–45) <i>M. musculus</i> (8e–45)
<i>Sp-vasa</i>	XP781494	CCHC Zinc Fingers (3–4), DEAD box helicases, conserved marker of germ cells, function unknown	<i>C. savignyi</i> (0) <i>D. rerio</i> (5e–152)

^aThe first BLAST score listed for each gene is the best hit and the second BLAST score listed is the best hit amongst organisms whose germ lines have been intensively studied.

Regeneration

Sea stars are famous for their regenerative capabilities. An adult may lose one or multiple of its arms, but as long as it has its central disk, it is capable of regenerating into an adult indistinguishable from an undisturbed adult. The loss of an arm may occur from predation, or by autonomy. If by predation and the arm is severed not at the central disk, the arm first repairs its wound, and then grows out to normal size as the undisturbed arms. How this mechanism works is not clear, but it must include mechanisms of wound healing, transformation of cell fates since each major structure within the arm recovers i.e., gonad, neurons, and skeletal surface tissues.

More recently it was learned that the larvae of many echinoderms can also effectively regenerate. Bisecting a larvae along the oral/aboral axis, or cutting perpendicular to the oral/aboral axis, results in larval segments able to restore its major cell fates and proceed through development. An advantage of exploiting the larval regeneration mechanism may be in timing; instead of weeks to see are regeneration in an adult, one can examine larval regeneration in the matter of a few days, and by visualizing all the cell types through the transparency of the larval body. Some of the results of studying this process are now being released and may lead to a molecular mechanism for regeneration to link to existing models e.g. the Planarian flatworm.

Maybe even more intriguing is that the larvae of some species have been shown to clone. That is, larvae will bud off a new organism from the body wall of the larva, and begin a new life on its own. It is not clear how productive the clone is; does it eventually metamorphose and will it make eggs and sperm? For more details on this phenomenon see [Evaes and Palmer \(2003\)](#).

Reproduction in Tunicates

Fabio Gasparini and Loriano Ballarin, University of Padova, Padova, Italy

© 2018 Elsevier Inc. All rights reserved.

Glossary

Atrial (peribranchial) chamber The space between the pharynx and the body wall collecting the exhaust water exiting the pharynx through the pharyngeal slits and conveying it to the atrial siphon.

Endostyle Ventral pharyngeal glandular groove secreting the mucous net covering the pharynx internal surface and entrapping the particles suspended in the incurrent water.

Gonoduct The tube connecting the gonad with the exterior, through which gametes are released.

Hermaphroditism The capability of an organism to produce both male and female gametes.

Notochord The dorsal, axial flexible rod of chordate embryos, serving as the major support during development and as a source of signals that pattern surrounding tissues.

Pharynx Anterior part of the digestive system, provided with many slits and involved in both filtration and gaseous exchanges.

Siphon Tube-like anatomical structure in which water flows. Tunicates have both an oral and an atrial siphon for incoming and expelled water, respectively.

Stolon A horizontal branch extruding from the base of an organism.

Reproduction in Tunicates

Tunicates or urochordates (Gittenberger and Sanamyan, 2017) form a subphylum of the phylum Chordata and are considered the closest relatives of vertebrates (Delsuc *et al.*, 2006). They are benthic or pelagic filter-feeding marine animals with indirect development. Tunicate owe their name to the tunic, the peculiar covering in which the body is embedded, whereas the name urochordates comes from the notochord, the dorsal supporting rod characterizing chordates, here limited to the larval muscular tail. The pharynx is well developed in the adult and, generally, occupies most of the body volume. Even if the internal interrelationship among the tunicate taxa is controversial (Stach *et al.*, 2010), they traditionally include the three classes Ascidiacea, Thaliacea and Appendicularia (Fig. 1).

Almost all the tunicate species have a tadpole swimming larva that metamorphoses into a strongly derived and specialized juvenile, with a dramatic change of the body organization (Stolfi and Brown, 2015).

In term of reproductive capability, the subphylum is characterised by the presence, unique among chordates, of asexual reproduction: several species are colonial with complex life cycle, and new zooids appear by budding from the somatic tissues of a pre-existing one (Brown and Swalla, 2012).

Fig. 1 Phylogenetic relationship among chordates. Red dashed lines represent possible relationships in uncertain branches.

Asciidiacea

Ascidians or sea-squirts (more than 5500 species) are sessile, marine invertebrates, including solitary and colonial species, diffused throughout the world, mainly in shallow tropical and temperate waters. At metamorphosis, the larval tail is resorbed, and the animals acquire a sac-like morphology. The body of the individuals or zooids ranges from 0.5 mm to more than 20 cm in length, that of colonial species being much smaller than solitary ones; it has a sac-like morphology mainly occupied by the fissured branchial chamber (the pharynx) and the flanking atrial (peribranchial) space, where the anus and the gonoducts open. The seawater flows from the oral siphon (the mouth), crosses the pharynx, enters the peribranchial chamber, and exits via the atrial siphon (Fig. 2).

In colonial ascidians, zooids can be either partially isolated and connected by stolons (deriving from the body wall and containing connective tissue and, sometimes, blood vessels) or partially or entirely embedded in the common tunic, frequently interconnected by a common circulation.

All ascidians are hermaphrodite, with simultaneous, protandric or protogynous hermaphroditism. Male and female gonads are usually distinct, although in some cases male and female tissues are present within the same, hermaphroditic gonad. Gonads may be unpaired, paired, or multiple and always have separate gonoducts that open into the atrial cavity. Their location varies and, even if this is a character no longer in use for the taxonomical subdivision of the group (Gittenberger and Sanamyan, 2010), ascidians may be distinguished on the basis of gonad position (Burighel and Cloney, 1997). Enterogona have gonads in close association with the intestinal loop, far from the atrial siphon, endowed with long gonoducts; in these species, sperms and eggs can be stored in the gonoducts before spawning. In Pleurogona, the gonads lie in the lateral body wall and are provided with short gonoducts (Fig. 3).

Ovaries are sac-like or tubular organs. Oocytes are surrounded by two layers (outer and inner) of follicle cells and an acellular vitelline coat; test cells are lodged between the plasma membrane and the vitelline coat.

Testes contain a system of branched tubules that end in blind, enlarged follicles (see Kawamura *et al.* (2011) for a detailed review of ascidian germline cell formation and differentiation). Sperms are uniflagellate, with small acrosome on the tip and a single mitochondrion, closely associated with the nucleus. In colonial ascidians, the sperm head is usually longer and more complex in structure, often with a coiled aspect (see Burighel and Martinucci (2000) for a detailed description of sperm ultrastructure). Sperm activation is accompanied by translocation of the mitochondrion towards the tail. Chemoattractants released by female gametes guide sperms to the eggs. Cross-fertilisation is the rule. Self-fertilisation, although reported in both solitary and colonial forms, is usually prevented by asynchronous maturation of male and female gametes. In some cases, gamete incompatibility exists.

External fertilisation takes place in solitary ascidians which, usually, have small eggs with little yolk. Inner follicular cells are greatly enlarged, highly vacuolated, and act as flotation devices. Spawning is usually triggered by light. Colonial species have internal fertilisation: sperms enter the peribranchial cavity through the atrial opening and reaches the oviducts. In this case, eggs are richer in yolk and, after fertilisation, embryos are brooded in the oviduct or in the peribranchial cavity. A few viviparous colonial species, with small alecithal eggs, have been described: in this case, parental zooids provide the nutrients required for embryonic development.

Cleavage is complete, of bilateral type. During gastrulation the blastopore, which marks the posterior part of the embryo, appears. Both the notochord, in the form of a solid rod, and the two muscular bands flanking the notochord, detach from the roof of the primitive intestine. A coelomic cavity never appears, and no mesoderm segmentation can be detected. The neural plate

Fig. 2 Ascidian metamorphosis. A swimming tadpole larva (A) adheres to the substrate (B) and metamorphoses into a sessile oozoid (C). In (B) the tail is retracting and the axial organs are pushed into the head. Modified from Ballarin, L., Burighel, P., 2003. Tunicata and Cephalochordata. In: Minelli, A., Contrafatto, G. sinks inwards and is covered by the ectoderm before it rolls up into a tube. The length of embryonic development is relatively short in solitary species (from some hours to a few days), whereas colonial species can brood their embryos for weeks or months. Free-swimming tadpole larvae hatch from the egg envelopes at the end of embryogenesis.

Although ascidians have high regenerating power, asexual reproduction is limited to colonial species. The oozoid, i.e., the first individual of a colony, deriving from metamorphosis of a tadpole larva, produce new zooids by budding. The resulting zooids are called blastozooids. Typically, a colony is a clone of genetically identical zooids and grows by continuous budding (Fig. 4).

Several modes of asexual reproduction have been described in different groups (Fig. 5) (see Brown and Swalla (2012) for a detailed review):

Stolonic budding, i.e., formation of buds from a branching stolon. Not common among ascidians; only found in Perophoridae.

Vascular budding, described in some botryllid ascidians. In this case, buds arise from aggregations of haemocytes (mainly lymphocyte-like cells) in tunic blood vessels.

Palleal or peribranchial budding, common in styelid ascidians. Buds derive from evagination of the mantle (i.e., the body wall, including the epidermis, the peribranchial epithelium and the mesodermal derivatives between them) at the sides of the body. In the genera *Botryllus* and *Botrylloides*, three blastogenetic generations are found in a colony: adult zooids with open siphons, buds and budlets, the latter coming from evagination of the bud body wall. At regular intervals, adult zooids close their siphons and are

Fig. 4 Life cycle of *Botryllus schlosseri*, a colonial ascidian. Modified from Gasparini, F., Caicci, F., Rigon, F., Zaniolo, G., Manni, L., 2014. Testing an unusual in vivo vessel network model: A method to study angiogenesis in the colonial tunicate *Botryllus schlosseri*. Sci. Rep. 4, 6460.

Fig. 5 Budding in ascidians. Modified from Nakauchi, M., 1982. Asexual development of ascidians: Its biological significance, diversity, and morphogenesis. Amer. Zool. 22, 753–763.

progressively resorbed in a process called takeover, while buds reach their functional maturity and open their siphons. Since a zooid gives rise to more than one bud, colonies progressively enlarge.

Budding by strobilation, widespread in the polyclinid and polycitorid ascidians. It involves fragmentation of the elongated body into two or more parts. Each part undergoes partial regression and dedifferentiation, then reorganises to form a complete individual.

Pyloric budding, typical of the didemnid ascidians. Two buds arise from oesophagus and abdomen, respectively. The oesophageal bud forms the new lower part of the body and the abdominal bud forms the new upper part. The two buds can either join together to form one zooid, or two zooids can form, each with an old and a new part.

Thaliacea

Thaliaceans are pelagic tunicates with complex life-cycle, alternating asexual and sexual generations (Deibel and Lowen, 2012). Their body is barrel-like, provided with wide oral and atrial openings at the opposite ends. The transparent zooids are embedded in a thin gelatinous tunic, so that circular bundles of muscles are easily visible. Members of this class include: Pyrosomatida, Doliolida (Cyclomyaria), and Salpida (Desmomyaria or Hemimyyaria).

Pyrosomatida

Pyrosomes, common in tropical and temperate seas, owe their name to luminescent organs which contain symbiotic bioluminescent bacteria. These bacteria enter the eggs and are transmitted to the new colonies. Colonies have the form of hollow cylinders with one blind end (Fig. 6).

Their size ranges from few centimetres to more than one metre in length. Zooids are located in the wall of the cylinder, embedded in the common tunic; the oral siphon of each zooid faces outwards, whereas the atrial aperture opens into the central cloacal cavity: water expelled through the cloacal aperture allows colonial locomotion by propulsion. The general structure of pyrosome zooids is quite similar to that of their ascidian counterparts: they are, hermaphroditic (an ovary and a testis lying ventrally, near the gut) and have a wide branchial basket occupying most of the body volume (Fig. 6).

Colonies grow by addition of new zooids that bud from a short stolon in the heart region of parental zooids. In a colony the oldest zooids are protandric and located near to the closed end; conversely, younger zooids are protogynous and located near the colonial opening, those in the middle are simultaneously hermaphroditic. Self-fertilisation is possible. Eggs, surrounded by both test and follicular cells, are provided with abundant yolk. Fertilisation is internal, and the zygote undergoes partial cleavage in a peribranchial pouch. A tadpole larva is missing and, at the completion of development, a goblet-like oozoid, named cyatozoid, is released from the atrial siphon. A stolon originates from its endostylar pharyngeal wall that buds four primary blastozooids. At this point the new colony reaches superficial waters and grows by repeated cycles of asexual reproduction.

Salpida

Salps live in all seas, from the surface down to 1500 m. About 200 species have been described; their size ranges from 1 to 20 cm in length. They are characterised by a metagenetic life cycle (i.e., they regularly alternate sexual and asexual generation). Similarly to pyrosomes, also salps lack a larval stage and the fertilised eggs develop directly into oozoids. The oozoids look like hollow

cylinders, open on the opposite sides (Fig. 7). The anterior, inhalant, opening can be closed by two lateral folds (velum). The pharynx is separated from the atrial chamber by a gill bar which lies obliquely between the posterior end of the endostyle and the anterior dorsal part of the body. The branchial and atrial cavities communicate through two large gill slits that, differently from other tunicates, are not bordered by cilia. Indeed, water flow is created by the contraction of striated locomotory muscles. The latter run transversely in the form of 4–8, ventrally incomplete, bands.

At the posterior ventral side of the oozoid, close to the gill bar, a whole opaque visceral mass forms the so-called “nucleus”; anteriorly, a stolon emerges, consisting of an outer epidermal sheet around an intermediate mesodermal layer and an inner endodermal axis derived from the endostyle. The stolon, by strobilation, forms a series of sexual blastozoids. In some periods of the year, rapid budding is responsible for salp blooms. Groups of buds are progressively formed: in each group, blastozoids are of the same age. Each group is weakly connected by some abortive buds, so that chains of several zooids are progressively released. In young chains, the blastozoids remain connected while feeding and growing; older chains may break into single zooids. In blastozoids the stolon is absent, a testis lies next to the nucleus and matures after the ovary (protogynous hermaphroditism), located on the right posterior side of the body. Internal fertilisation occurs by sperms from older zooids penetrating the pharyngeal cavity with incoming water. In most species, they reach the egg through a solid oviduct. Cleavage of the alecithal eggs is holoblastic. A placenta is formed, which connects the embryo to maternal tissues, and development occurs within the maternal cloacal wall. In most cases, a single embryo is directly exposed to the cloacal cavity, where the young oozoid is finally released before being expelled outside.

Doliolida

Doliolida are small (0.5–5 cm in length) pelagic forms living in warm superficial waters. About 50 species have been described. Doliolids are unique among thaliaceans in having a free larval stage. Like other members of the class, doliolids alternate sexual and asexual generation, but their life-cycle is much more complex than in other thaliaceans, as various blastozoid bud types derive from oozoids (Fig. 8). The life cycle starts with a barrel-shaped oozoid which indirectly derives from the fertilised egg, after the metamorphosis of a free-swimming larva. A thin tunic covers the outer epidermis. Nine muscular bands (eight in blastozoids), easily visible through the transparent body, lie under the epidermis of the oozoid: the first and the last form the oral and atrial sphincters. Contraction of the muscle bands allows locomotion by jet propulsion. Both anterior and posterior apertures bear a row of flaps, provided with ciliated sensory cells, which can distally converge when the sphincters contract and close the openings. The internal cavity is divided by a transverse branchial septum into an anterior pharyngeal space, of endodermal origin, and a posterior, ectodermal atrial (cloacal) region. The gill is perforated by two rows of wide, ciliated slits. Beating of cilia bordering gill slits causes water to flow from the oral opening to the cloacal cavity through the branchial septum.

Oozoids bear a small ventral stolon and a dorsal, posterior appendix. As they age, most of the visceral organs (endostyle, branchial septum, gut) disappear, and the animals can no longer feed. At this stage, the ventral stolon continuously produces new buds by strobilation. Carried by special migrating cells, phorocytes, they travel around the right posterior side of the adult body to the dorsal appendix, and are arranged in three symmetrical rows in the dorsal surface of the appendix. The buds of the outer rows develop into gastrozooids or trophozooids, with enlarged pharyngeal region for nourishment of the whole colony, represented by the old oozoid and its growing blastozoids. Gastrozooids stick to the parental oozoid via a ventral mass of epidermal cells, called the placenta. The latter presumably ensures the exchanges of nutrients between gastrozooid and oozoid. Buds of the central row mature into phorozooids with ventral budlets. They can feed themselves and detach from the parental oozoid to form a free colony made up of the phorozooid and its buds. The latter grow to free-living gonozooids which represent the sexual generation. Gonozooids are protogynous hermaphrodites; their single ovary produces up to three eggs which, once fertilised, are released into the atrial cavity and then into the sea, before maturation of the testis. Fertilisation is followed by rapid embryonic development,

Fig. 8 General morphology of Doliolids. Modified from Alldredge, A.L., Madin, L.P., 1982. Pelagic tunicates: Unique herbivores in the marine plankton. *BioScience* 32, 655–663.

which leads to a free larva living in deep waters. Most doliolid larvae possess a muscular tail provided with a notochord. At metamorphosis, the larval trunk progressively assumes the barrel shape of the oozoid and the tail is resorbed. A new oozoid is thus formed and a new life-cycle starts.

Larvacea or Appendicularia

Larvacea or Appendicularia (about 70 species) are free-swimming, highly specialised, pelagic Tunicates found in all the oceans (Deibel and Lowen, 2012). The name Larvacea refers to the close similarity of adult Appendicularia with the ascidian tadpole larva, their body being formed of a “trunk”, 1–4 mm long, and a much longer tail (Fig. 9); in larger species, the animal may reach a total length of 6–8 cm. A remarkable feature of larvaceans is their constant cell number (euthely). They include three groups: Oikopleuridae (the most studied Appendicularians; Onuma *et al.*, 2017), Fritillariidae and Kowalewskidae.

The main feature of Appendicularia is the ‘house’, which is secreted and inhabited by the animal itself. This gelatinous structure is secreted by a specialised area of the epidermis of the trunk: the oikoplast, where large glandular cells are located. The house, mainly formed by mucopolysaccharides, is secreted in a condensed form as a gelatinous cap covering the anterior half of the trunk; it rapidly inflates (in a few seconds) due to animal movements and water absorption, thus increasing its volume about 300 times. In Oikopleuridae and Kowalewskidae, the whole body enters the house, whereas in Fritillariidae animals are external to the house, that resembles a large ball connected to the mouth. Houses act as filtering devices and traps for food. The tail acts as a muscular pump, sucking water into the house through two dorsal openings provided with coarse filtering grids to prevent oversized or harmful material from entering the house with incoming water currents. Water is driven into the posterior chamber and forced through two fine-meshed nets which trap and concentrate suspended particles, less than 5 µm in size. Outflowing water, leaving the posterior chamber, propels the whole house in such a way that the animal’s mouth, oriented towards the mucous traps, is directed posteriorly. A food-collecting tube connects the food filters with the mouth, and a weak water current, generated by the cilia lining the pharyngeal openings (spiracula), allows particles to reach the mouth and the pharynx, where they are re-captured by the mucous net secreted by the endostyle, before entering the oesophagus. When the filters clog, after some hours of filtration, houses are shed and replaced by new ones: up to five houses can be produced in one day.

Only sexual reproduction occurs in Larvacea, and all of them, apart from the only known tunicate gonocoric species *Oikopleura dioica*, are protandric hermaphrodites. The gonads lie in the posterior part of the trunk (Fig. 9): sperm is released through a dorsal

Fig. 9 Schematic representation of oikopleurid Appendicularia. Modified from Ballarín, L., Burighel, P., 2003. Tunicata and Cephalochordata. In: Minelli, A., Contratatto, G. (Eds.), *Biological Science Fundamentals and Systematics*. Oxford: Eolss Publishers. Available at: <http://www.eolss.net>.

spermiduct, whereas eggs are released by rupture of the trunk wall, which causes the death of the animal. External fertilisation occurs, and development gives rise to a tadpole larva which rapidly undergoes simple metamorphosis, involving a change in tail orientation and acquisition of competence for secreting 'houses'.

Introduction

Chondrichthyes are cartilaginous fish within the vertebrate lineage that are divided in two sub clusters: Elasmobranchs including sharks, rays and skates and Holocephali including the chimaeras. Chondrichthyes have survived and avoid mass extinction for over 400 million years, being one of the most successful and oldest group of vertebrates in terms of historical durability. This lasting success has largely depended on their diverse reproductive adaptations developed during their long evolutionary history. Why? Because the primary requirement for successful survival of any species is their ability to reproduce and give birth to fit newborns that will contribute to future generations. Understanding the process of reproduction requires knowledge of the chondrichthyan species' reproductive adaptations where the most effective adaptation is one that produces as many fit progeny as necessary to ensure species survival in any giving aquatic environment. Chondrichthyans developed different reproductive adaptations, and although generalizations of these reproductive strategies are difficult as many species uncover unique adaptations, shared grounds can be distinguished. The reproductive strategies are expressed through a combination of a wide range of reproductive modes and reproductive cycles. These reproductive modes are classified based on embryo development sites and embryo nourishment. According to embryo development sites, two categories can be distinguished: oviparity, where females lay eggs that typically develop and hatch outside the maternal body; and viviparity, where embryo development occurs inside the maternal body and females give birth to fully developed newborns. According to embryo nourishment throughout its development, these two reproductive categories are further divided as lecithotrophy, where the nutrients are supported solely by a yolk-sac with no maternal input; and matrotrophy, where at least part of the embryo nourishment are supplied by maternal input of nutrients.

The reproductive cycles denote the beginning to the end of each reproductive phase, combining: (1) the length of follicle development within the ovary that will be fertilized to form the embryos, (2) mating/fertilization, (3) the subsequent egg deposition/pregnancy period, and (4) a resting period preceding a new follicle development cycle (not all species have resting periods).

Finally, although out of the scope of this chapter, it is important to mention that the brain-pituitary-gonadal axis is a cascade system that triggers and regulates the entire reproductive process, promoting follicle production, ovulation, mating, fertilization, embryo development, and parturition.

Classification of Reproductive Modes

One of the most important reproductive physical adaptation in the evolution of chondrichthyans is the modification of the male pelvic fins into claspers (copulatory organs) allowing for internal fertilization. As a consequence, it is likely that chondrichthyans developed early in the evolution a viviparity reproductive mode, which has been confirmed by finding that multiple forms of viviparity are the ancestors of oviparity in both Elasmobranchii and Holocephali (Grogan and Lund, 2011).

Oviparity

Approximately 42% of Chondrichthyan species (including all Holocephali) are oviparous (Compagno, 1990; Dulvy and Reynolds, 1997). Oviparous species produce eggs that are enclosed in resilient egg cases for deposition on the seabed. The cases also contain the egg "jelly," a gelatinous material that serves as hydrodynamic support for the egg/embryo during early development. Embryo development occurs inside these egg cases and normally outside the maternal body (Fig. 1). Two forms of oviparity have been described, single (or extended) and multiple (or retained) oviparity. The majority of the oviparous species (39%) follow a single oviparity where one egg case is deposited at a time from each uterus with no embryonic development until the egg case is laid. Multiple oviparity has been found in nine elasmobranch species; females produce one or several eggs cases (each case contains one embryo) that, instead to be laid, are retained in the uterus where embryos develop to an advanced stage inside the maternal body. After egg cases deposition, embryo development is finalized in a relatively short time outside the maternal body.

According to embryo nutrition, all oviparous species are lecithotrophic, nutrients are supplied solely by the yolk-sac (Fig. 1). The yolk-sac is like a small balloon full of nutrients produced by the maternal liver and transfer to each follicle during its development. Once the follicles complete their development, follicles are ovulated and fertilized, the embryo starts to develop and the yolk remains as a sac attached to the embryo stomach transferring nutrients. As the development progresses yolk absorption is almost complete at hatching (Fig. 1).

Parental care is not evident in oviparous elasmobranchs (Jacoby *et al.*, 2012) therefore, embryo survival relies on the maternal selection of the appropriate environment for egg case deposition and posterior hatching.

Fig. 1 Left Photo: Egg cases deposited from sharks. It can be seen inside the egg/embryo (E). Right Photo: Open egg case, late development embryo stage and yolk-sac (YS) visible. Photos by C.A. Awruch.

Viviparity

Viviparity is a highly successful reproductive mode and is the dominant form of reproduction found in approximately 58% of elasmobranchs (Compagno, 1990; Dulvy and Reynolds, 1997). The main characteristic of viviparous species is that embryo development occurs inside the maternal body. In live-bearing species, females invest and allocate higher energy resources to sustain larger size embryos than in oviparity. The evolutionary advantages of larger birth sizes are to improve embryo survival, with greater ability to prey and fewer predators at birth. As with oviparous species there is no evidence suggesting parental care of any sort following parturition.

According to embryo nutrition, viviparity can be divided into two main categories.

(1) *Lecithotrophic Yolk-Sac Viviparity*

Yolk-sac viviparity occurs in about 18% of living elasmobranch species (Hamlett and Koob, 1999). The embryo develops within the mother's uterus, providing the environment where oxygen supply, osmoregulation (water and inorganic ions exchange), and waste removal occurs. However, the maternal uterus does not provide nutrients. Thus, as with oviparous species, nutrients are supplied solely by the yolk-sac attached to the embryo (Fig. 2(A)).

The embryo development occurs in two stages. The initial gestation stages are called the pre-eclosion stage. Once ovulation and fertilization is completed, the egg/embryo is encapsulated in a "candle", an elongated, thin and translucent capsule (Fig. 2(B)). In

Fig. 2 Lecithotrophic yolk-sac viviparity. Illustrated by M.C. Sueiro.

general, the maternal females hold one candle per uterus, but the number of embryos that each “candle” can hold varies between species. For example, in the hidden angel shark, *Squatina occulta*, two to six embryos are enclosed in each candle (Sunye and Vooren, 1997), while, and very interestingly, a pregnant whale shark, *Rhinocodon typus*, was found to carry about 300 embryos many of which were still enclosed in individual cases (Joung *et al.*, 1996). Initial stages of embryo development occurs within the “candle”, after which, the “candle” breaks releasing the embryo freely into the maternal uterus to continue developing until parturition (Sunye and Vooren, 1997).

(2) Matrotrophic

This strategy occurs in around 40% of viviparous elasmobranchs. As with yolk-sac species, during the early stages of embryo development, nutrients are supplied by the yolk-sac, and once these are exhausted, the mother will supply nutrients through a variety of mechanisms: uterine secretions (histotrophy); unfertilized eggs (oophagy) or sibling (adelphophagy); and placental transfer (placentatroph).

The main advantage of matrotrophic reproduction is that embryos can gain significant weight and size during their development, in comparison with solely yolk-sac nutrition.

Histotrophy: The majority of the matrotrophic elasmobranchs follow this uterine secretion reproductive mode. The maternal uterus secretes into the intrauterine lumen nutritive organic fluid known as “uterine milk” or histotroph, which is consumed by the embryo by either ingestion or absorption across the external gill filaments.

Very recently a new possible type of reproductive mode according to embryo nutrition has been categorized, embryotrophy (Castro *et al.*, 2016). Up to date, this type of reproduction has only been observed in one species of sharks, the tiger shark *Galeocerdo cuvier*. In this type of nutrition, the egg case, a yellowish and thin membrane that surrounds the embryo throughout development, becomes filled early in the gestation with a large quantity (about one liter) of a clear yellowish fluid, embryotrophe. This embryotrophe is the maternal source of nutrition for the embryo after the yolk-sac has been consumed. However, although is likely that embryotrophe is secreted by the maternal uterus, more studies on the secretory function of the uterine epithelium needs to be done. Until then, this new reproductive mode cannot completely being confirmed.

Oophagy: This reproductive mode occurs only in sharks. Once the embryo depleted the yolk-sac reserves, the mother provides a constant supply of unfertilized and undeveloped eggs that will disintegrate providing exogenous yolk as a source of nutrition for the developing embryo.

Adelphophagy (also called embryophagy or intrauterine cannibalism): This reproductive strategy is a form of oophagy, where the mother produce few fertilized and unfertilized eggs as a source of nutrition (Fig. 3(A)). This type of reproduction has been, so far, identified in only one shark species, the grey nurse shark, *Carcharias taurus*. In this species, the gestation last 12 months, the mother produces fertilized eggs to form the embryos in the first 2.5 months, however only one embryo will develop teeth within the first 5–6 months which allows the embryo to consume the other siblings inside the maternal uterus, the embryophagous stage. Once the siblings are consumed, the embryo will use the yolk from the unfertilized eggs as a source of nutrients, the oophagous stage. A single embryo develops in each uterus. (Gilmore *et al.*, 2005).

Fig. 3 Matrotrophic reproductive mode. (A) Adelphophagy. (B) Placentatroph. Illustrated by M.C. Sueiro.

Placentotrophy: This reproductive strategy occurs only in sharks. Generally involves a 12-month gestation period. During the first months of gestation, each embryo is enclosed in a separate thin and translucent capsule feeding the yolk-sac. Once the yolk is consumed, the embryo shift to an uterine milk (histotroph) source of nutrition. At the same time, the uterus compartmentalized surrounding each capsule/embryo while the sac (from the yolk-sac) modifies to form a placenta-like connection with the maternal uterus. The embryo will receive maternal nutrients until the end of the gestation through this placental structure (Fig. 3(B)).

Reproductive Cycles

A reproductive cycle is defined as a series of events that an organism must undergo in order to successfully reproduce. These events are regulated by physiological, genetics and environmental factors with the ultimately goal to produce a surviving progeny. In chondrichthyan females, these events are the ovarian cycle (follicle development for ovulation); mating; embryo gestation and parturition in viviparous species and egg case formation, retention and oviposition in oviparous species; and a possible final resting period preceding a new ovulatory cycle.

According with the timing of the reproductive cycles, chondrichthyan females are categorized in two main categories: (1) continuous breeders and (2) seasonal breeders.

Continuous Breeders: In this category, species can be: (i) reproductively active throughout the year or (ii) reproductively active throughout the year, but with seasonal periods where a greater proportion of reproductive activity occurs. Continuous breeders include both oviparous and viviparous species. For example, while the oviparous small-eyed catshark, *Apristurus microps*, lays eggs all year round (Ebert *et al.*, 2006), the draughtboard shark, *Cephalloscyllium laticeps*, lays eggs in pairs at monthly intervals throughout the year but shows a peak in egg deposition between January through June (Awruch *et al.*, 2009).

In viviparous continuous breeders, pregnancy lasts nearly a full year, with mating and the subsequent pregnancy ensuing soon after parturition. For example, the Pacific angel shark, *Squatina californica*, displays an annual reproductive cycle with a 9–12 months gestation period (Natanson and Cailliet, 1986), and while the spiny dogfish, *Squalus acanthias*, does not have an annual cycle, still display a continuous biannual cycle with a 22-month gestation period and mating occurring every two years (Chatzisprou and Megalofonou, 2005).

Seasonal breeders: As with continuous breeders, seasonal breeders comprise oviparous and viviparous species. In this type of reproductive cycle, species can be divided as: (1) species with a well-defined seasonal cycle, where animals are laying eggs/pregnant for only a portion of the year, and (2) species that are pregnant for approximately a full year, after which they spend a year or two non-pregnant. For example, in the oviparous epaulette shark, *Hemiscyllium ocellatum*, (Heupel *et al.*, 1999) the egg laying season occurs during a 6-month period of the year, while in the Port Jackson shark, *Heterodontus portusjacksoni*, the season only last 1–2 months of the year (Powter and Gladstone, 2008). In viviparous species such as the Atlantic stingray, *Dasyatis sabina*, the pregnancy last 5–6 months within a year cycle (Snelson *et al.*, 1997), while in the sandbar shark, *Carcharhinus plumbeus*, pregnancy last one year followed by one year of non-pregnancy, thus the reproductive cycle last two years (McAuley *et al.*, 2007).

Ovulatory cycles: The ovulatory cycle in chondrichthyans is defined as the period that involves follicle development (the accumulation of yolk by each follicle until reaching ovulation size), ovulation and a possible resting/dormant phase preceding the new follicle cycle.

In oviparous species, the events of ovulation, egg formation and encapsulation last 24–48 h. Thus, follicle development runs continuously throughout the year in oviparous species with a continuous reproductive cycle. While in oviparous seasonal species, follicle cycles occur between the egg production/laying periods with a possible resting/dormant phase in between. As these periods could last weeks or months, later stages of follicle development occurs in parallel with egg production during the laying period. After the last oviposition of the season, females can reach a dormant/resting phase that can last for weeks or several months preceding the new follicle development cycle (Fig. 4).

In viviparous continuous breeders, a significant proportion of follicle development for the subsequent pregnancy occurs concomitant with gestation, thereby allowing ovulation to occur soon after parturition. In species with seasonal cycles, follicle development is temporally separated from pregnancy and occurs well after parturition, allowing females to have a dormant/resting phase immediately after parturition before starting the new follicle development and gestation cycle.

Mating and parthenogenesis: The whole point of mating in chondrichthyan species is the successful deposition of semen by the clasper inside the female's reproductive tract producing offspring that share similar traits with their parents but are genetically diverse. This genetic diversity will increase the progeny fitness, and thus, the species survival throughout generations. After mating, sperm storage has been frequently reported in chondrichthyans. Female sperm storage is an important phase in the reproductive process enabling mating, ovulation, and fertilization to occur at different times. The time of sperm storage varies between species and can be as short as 5–6 weeks to, at least, more than two years (Pratt and Carrier, 2005).

In recent years, parthenogenesis, a form of asexual reproduction in which the production of offspring occurs in the absence of fertilization has been confirmed in increasing number of elasmobranchs. Females produce unfertilized eggs, with any male genetic contribution, that will develop into viable embryos. In the last 10 years, facultative parthenogenesis, the occurrence of asexual reproduction in otherwise sexually producing species, has been confirmed in six elasmobranch species. For example: the hammerhead shark *Sphyrna tiburo* (Chapman *et al.*, 2007) the whitetip reef shark *Triaenodon obesus* (Portnoy *et al.*, 2014) and very recently in the zebra shark *Stegostoma fasciatum* (Dudgeon *et al.*, 2017).

Fig. 4 Ovulatory cycle in oviparous chondrichthyans. (A) Continuous ovulatory cycle: Follicle development runs parallel with ovulation, capsule formation and oviposition. Follicles in all stage of development are present in the ovary. Follicles full of yolk ready to be ovulated are present throughout the year (top line photos). Recently formed egg cases can be distinguished inside the uterus (bottom line photos). (B) Seasonal ovulatory cycle: Follicle development runs in parallel with encapsulation only during the egg-laying period. The dormant/resting stage is characterized by the ovary carrying very small undeveloped follicles. E, Egg case; F, Follicle. Photos by C.A. Awruch.

While increasing cases of parthenogenesis have been reported in elasmobranchs, the benefits of this reproductive strategy remains unknown. Although, the ability for females to reproduce through facultative parthenogenesis would be selectively advantageous in situations where females have no other available options for passing on genes (e.g. absence of males), very little is known about the long-term viability of parthenogenesis where a reduction in genomic diversity could reduce the progeny fitness. A challenge for understanding the adaptive nature of facultative parthenogenesis is identifying the internal and external conditions that may trigger this, still quite unusual, reproductive strategy in elasmobranchs.

Glossary

Gonoduct A pair of tubes that comprise the female reproductive tract that extends from their anterior, funnel-like openings to the cloaca.

Gonochoresis Having distinct female with ovaries and distinct male with testes in a given species.

Polygamy A mating system in which one sex mates with several partners.

Protandry When an individual starts as a sexually mature male, producing sperm, but at some time in its life it becomes a functional female.

Protogyny When an individual starts as a female, spawning eggs, but then later changes into a functional male, producing spermatozoa.

Sequential hermaphrodite A fish that first develops as one sex, but changes to the opposite sex at some point in life.

Introduction

The fishes are the most diverse group of vertebrates. Currently, >33,000 species are recognized in the online resource FishBase, which is close to 50% of all known vertebrate species. Of these, the Teleostei (teleosts), or the modern bony fishes are the majority and are represented by ~27,000 species. Osteichthyes is a taxonomic class of fish that includes the ray-finned fish (subclass or class Actinopterygii) and lobe-finned fish (subclass or class Sarcopterygii). Recent phylogenetic analysis is leading to reclassification of many fishes, and places the origin of Sarcopterygii and Actinopterygii in the Middle Silurian, with the sarcopterygian crown group evolving in the Early Devonian (~409 million years ago) and the actinopterygian crown group evolving at the Middle-Late boundary of the Devonian (~383 million years ago), both of which correspond to the Age of Fishes (Betancur *et al.*, 2017). The reader can consult the newest classification of bony fishes in Betancur *et al.* (2017) which is open-access and online (Fig. 1 is especially relevant). The living sarcopterygians are two species of coelacanth and six species of lungfish. There are clear evolutionary relationships with lungfishes and tetrapods, especially amphibians, but there remains considerable debate amongst evolutionary biologists as to the relationship relationships among lungfishes, coelacanth, and tetrapods. Actinopterygii can be broadly divided into the Neopterygii and the Chondrostei. According to Nelson (2006), the Neopterygii includes the typical bony fishes, the Teleostei as well as Amiiformes (bowfin) and Lepisosteiformes (gars). Given that the teleosts are the largest group, represented by many commercially important species, and that the vast majority of our information on fish reproduction comes from the study of these species, most of this article is focused on them. The Chondrostei include Acipenseriformes or the sturgeons, and Polypteriformes or the bichirs.

The Cyprinidae (carps and minnows) and the Gobiidae (many are bottom-dwelling gobies), are teleost and represent the largest vertebrate families in terms of number of species (Wootton and Smith, 2015). The vast array of colors and body forms, and reproductive strategies (Table 1) exhibited by fish attracts considerable attention from evolutionary biologists, zoologists, and those interested in fish culture (aquaculture and hobby aquaria). Sex determination is the process by which the sex of an individual is established early in development, be it genetically or environmentally. Many teleosts have genetic sex determination, meaning that female or male development is determined by a gene or a complex series of genes. Genetic sex determination is the typical condition in vertebrates, for example, the well-known X and Y chromosome system in most mammals, including humans. On the other hand, a good number of teleosts exhibit environmental sex determination, where factors such as temperature change promotes the development of one sex or another. This phenomenon, known as temperature-dependent sex determination, was first reported in *Menidia menidia* (Table 1), a species belonging to the family Atherinopsidae (Blázquez and Somoza, 2010). The pejerrey, *Odontesthes bonariensis*, is an Argentine silverside in the same family with strong temperature-dependent sex determination. In this species, sex ratios reach 100% female or 100% male at environmentally relevant temperatures of 17 and 29°C, respectively. Recently, the coexistence of genetic and temperature-dependent sex determination has been demonstrated in this pejerrey (Yamamoto *et al.*, 2014). This indicates that the environment can change the genotypic sex of the fish, leading to the existence of genotypic males but phenotypic females and, vice versa. However, the evolutionary significance of this is still under debate.

By far, the bony fishes exhibit the greatest diversity of reproductive patterns among the vertebrates (Denski, 1987; Devlin and Nagahama, 2002). Most species are gonochoristic meaning that they have the familiar distinct female with ovaries and male with testes (Fig. 1), forming monogamous pairs at spawning time. In one unusual example, the deep-sea anglerfish, the very small male attaches himself (fusion of his jaw to the female's body) to the large female who probably takes over control of his reproductive system (Denski, 1987). There are teleosts that are sequential hermaphrodites, starting off as one sex, and changing permanently to the other sex. In the case of protogyny, the animal is first female, then transforms into a fertile male. For protandry, the animal is first male and then transforms into a female. Although far less common than the previously mentioned modes of reproduction, there are also simultaneous hermaphrodites where individuals trade sperm and eggs during spawning, or where an individual can self-fertilize under natural breeding conditions. Given the dazzling variety of these fishes, it is impossible to cover all aspects.

Fig. 1 The zebrafish *Danio rerio* (family *Cyprinidae*) as an example of a gonochoristic teleost. Zebrafish, also known as the zebra danio, originates from Pakistan, India, Bangladesh, Nepal and Myanmar. It is a common aquarium species, and is an important model species for scientific research on the mechanisms of development and reproduction in vertebrates. A: Sexually mature adult female. B: Sexually mature adult male. C: Dissection of the sexually mature adult female showing the large ovary outlined with the white line. D: Dissection of the sexually mature adult male showing the testis outlined with the white line. Photo credit: Mitchell K., Benson, P., Trudeau, V.L. (July 2017).

Therefore, the main objective of this article is to provide a brief overview of reproduction in bony fishes. The reader is also directed to Wootton and Smith's book titled *Reproductive Biology of Teleost Fishes* (2015), which is an excellent and comprehensive resource, one upon which this short overview is based.

Gender Systems

About 90% of Osteichthyes have a distinct female with ovaries and distinct male with testes. This is known as gonochorism. Following the early stages of sex determination, a gonochoristic fish develops either testes or ovaries, and after puberty they reach maturation. They have the ability to produce fertile sperm and eggs, and spawn to give rise to the next generations. The time to reach sexual maturation is highly variable amongst the various teleost species; for example, the fastest known is the goby *Schindleria praematura* from Okinawa, Japan, maturing in less than 2 months, which can be contrasted to European eels (*Anguilla anguilla*), which can be blocked in a pre-pubertal state for many years until environmental cues activate secretion of reproductive hormones, and then the eels migrate to their ocean spawning site (Dufour *et al.*, 2003). The white sturgeon *Acipenser transmontanus* from western North American can live to over 100 years old. They grow slowly and are not ready to spawn until the females are over 18 years of age and males are at least 14 years of age.

One usually associates the word hermaphrodite with ambiguous sex organs in humans, although nowadays a more acceptable term is the intersex person. Historically, the word hermaphrodite derives from the Latin: *hermaphroditus*, and from Ancient Greek *hermaphroditos* which itself comes from *Hermaphroditus*, the son of Hermes and Aphrodite in Greek mythology. According to the story *Hermaphroditus* fused with the nymph *Salmacis*, giving rise to one individual possessing physical traits of

Table 1 Sex and mating strategies in bony fishes

Sexuality or mating system	Example
1. Sex determination	
(a) Genetic	Most teleosts
(b) Environmental	Atlantic silverside, <i>Menidia menidia</i>
2. Gender systems	
(a) Gonochorism	Most teleosts
(b) Hermaphroditism	
(i) Simultaneous (synchronous)	
Self-fertilizing	Mangrove rivulus, <i>Kryptolebias marmoratus</i>
Outcrossing	Barred Seabass, <i>Serranus fasciatus</i>
(ii) Sequential	
Protogynous	Blue-headed wrasse, <i>Thalassoma bifasciatum</i>
Protandrous	Red and Black Anemonefish, <i>Amphiprion melanopus</i>
Serial (bidirectional)	Rippled Coral Goby, <i>Gobiodon rivulatus</i>
3. Modes of fertilization	
(a) External	Most teleosts
(b) Internal	Common guppy, <i>Poecilia reticulata</i>
(c) Buccal	Tilapia, <i>Oreochromis niloticus</i>
4. Mating systems	
(a) Promiscuity	Atlantic herring, <i>Clupea harengus</i>
(b) Polygamy	
(i) Polygyny	Tilapia, <i>Oreochromis niloticus</i>
(ii) Polyandry	Common guppy, <i>Poecilia reticulata</i>
(iii) Polygynandry	European bitterling, <i>Rhodeus amarus</i>
(c) Monogamy	Convict cichlid, <i>Amatitlania nigrofasciata</i>
5. Secondary sexual characteristics	
(a) Monomorphism	Atlantic herring, <i>Clupea harengus harengus</i>
(b) Sexual dimorphism	
(i) Permanent dimorphism	Siamese fighting fish, <i>Betta splendens</i>
(ii) Temporary dimorphism	Common goldfish, <i>Carassius auratus</i>
6. Spawning site preparation	
(a) No preparation	Eurasian minnow, <i>Phoxinus phoxinus</i>
(b) Site prepared, but not defended	Atlantic salmon, <i>Salmo salar</i>
(c) Site prepared, and defended	Three-spined stickleback, <i>Gasterosteus aculeatus</i>
7. Parental care	
(a) No care	Most teleosts
(b) Paternal care	Three-spined stickleback, <i>Gasterosteus aculeatus</i>
(c) Maternal care	
(i) Oviparity	Tilapia, <i>Oreochromis niloticus</i>
(ii) Viviparity	Common guppy, <i>Poecilia reticulata</i>
(d) Biparental care	Convict cichlid, <i>Amatitlania nigrofasciata</i>
(e) Juvenile helpers	Kambwimba or daffodil cichlid, <i>Neolamprologus pulcher</i>

both a man and a woman. In a few fishes, the condition of hermaphroditism is a successful reproductive strategy. An unusual case is simultaneous (synchronous) hermaphroditism in the mangrove rivulus, *Kryptolebias marmoratus*, common along the coastal regions of Florida, the Caribbean and the eastern coasts of Central and South America. Mangrove rivulus exist primarily as hermaphrodites with preferential internal self-fertilization but the species exhibits environmental sex determination, with primary males developing from embryos incubated at low temperatures (18–20°C; Harrington, 1961).

Far more common are sequential hermaphrodites, especially in many coral reef fishes (Wootton and Smith, 2015). Some species with simultaneous hermaphroditism do outcross, mating with other individuals. Another unusual case is the barred seabass, *Serranus fasciatus* (Petersen, 1990). All individuals start life as simultaneous hermaphrodites, but the largest individuals in any location lose femaleness and change to become functional males. These males guard territories containing 1–8 hermaphrodites that they defend against other males. Barred seabass males pair-spawn with hermaphrodites within their harem (Petersen, 1990).

Sex change is documented in about 2% of teleost species spanning over 20 families (Liu et al., 2017). Such functional sex changes generally follow one of three patterns (Table 1): protogynous (female-to-male), protandrous (male-to-female), and sequentially bi-directional. Protogyny is when an individual starts as a female, spawning eggs, but then later changes into a functional male, producing spermatozoa. Protandry on the other hand describes the situation in which an individual starts as a sexually mature male, producing sperm, but at some time in its life it becomes a functional female.

A well-known example of a protogynous species is the blue-headed wrasse, *Thalassoma bifasciatum*, in the Gulf of Mexico and Caribbean regions. In this species, social conditions control the sexual transformation. In the blue-headed wrasse, one territorial terminal-phase male dominates a number of lower-ranking females. When the dominant male disappears (e.g., fishing, predation, etc.), one of the largest females in the area takes over and changes its sex to male. This is a rapid change in reproductive behavior, gonadal anatomy, and external body morphology. Please consult figure 1 in the research article by Liu *et al.* (2017), where this dramatic change is well-depicted and explained. In this wrasse, the first sign (minutes to hours) of the impending sex change is the temporary display of spawning colors (a bluish head and darkening of fin tips) and expression of terminal phase male-typical behaviors of aggression and courtship. Tissues of the ovary of this new dominant female start to disappear within 3 days, while development of the testes and external colors typical of sexually active males start by days 4–6. Sex changers can have functional testes filled with sperm in 8–10 days and the whole process is usually complete within 3 weeks (Liu *et al.*, 2017).

A recognizable protandrous fish is the Red and Black Anemonefish, *Amphiprion melanopus*, made famous in the 2003 Walt Disney film *Finding Nemo* (A. Stanton and L. Unkrich, directors). The anemonefishes form a specialized subfamily, the Amphiprioninae, within the damselfishes (Pomacentridae) and they are famous for their symbiotic relationship with large tropical sea anemones in the Western Pacific. This unusual association has produced a mating system unique among tropical reef fishes. Sex is controlled socially in *Amphiprion melanopus* (Godwin, 1994). Females are always the largest and the behaviorally dominant individuals in a group and disappearance or removal of the female allows sex change to proceed in her mate, a mature male that will become the new female. The dominant sub-adult individual in a group then matures and takes over the male breeding role. Detailed histological studies have shown that complete transition from male to female function in *Amphiprion melanopus* takes place in between 45 and 100 days. This seems to be true for the other species of *Amphiprion* (Godwin, 1994). In some serially changing species, the switch between male and female can take place more than once in a lifetime to favor reproductive success. The Rippled Coral Goby, *Gobiodon rivulatus*, from the Indo-West Pacific region is a good example. Males take care of eggs deposited on coral branches.

Modes of Fertilization

The most common mode of fertilization in teleost fishes is external. After courtship and sexual displays coordinated by environmental factors and sex pheromones, female and male release eggs and sperm for rapid fertilization. The biology of eggs and sperm is variable between fish species and the processes leading up to fertilization are often very different compared to mammals. For example, salmon and trout eggs are very large relative to sperm, and eggs are fertilized after the first sperm cell enters a single opening (the micropyle) in the egg membrane which is barely wide enough to allow entry of one sperm cell (Hoysak and Liley, 2001). Another notable characteristic of salmonid reproduction is the limited lifespan of the eggs and sperm. Hoysak and Liley (2001) studied this under experimental conditions in the sockeye salmon *Oncorhynchus nerka*, a well-known commercial fish species of the West coast of North America. In sockeye salmon, eggs had a very limited longevity after being immersed in water, with a large drop in fertility occurring after 20 s of exposure to water. Sperm had an even shorter period of fertility. They maintained high fertility for 10 s after being exposed to water but fertility dropped sharply after that. The fertilization of an egg by a sperm occurs very rapidly where 80% fertilization success was achieved with 5 s of sperm-egg mixing. In this example, the brief window of time during which eggs remain viable make position and timing critical for male reproductive success under the intense conditions of sperm competition in sockeye salmon (Hoysak and Liley, 2001) and other externally fertilizing fishes.

According to Wootton and Smith (2015) fertilization takes place internally in the female in about 500–600 teleost species. The male introduces the sperm into the gonoduct of the female, using a specialized intromittent organ. This is analogous to the mode of fertilization seen in the cartilaginous fishes, the Chondrichthyes, and in mammals and a few other vertebrates. In the guppy, *Poecilia reticulata* and the related poeciliid, the green swordtail *Xiphophorus hellerii*, common as aquarium fishes, the anal fin in males is shaped into a grooved, rod-shaped organ called a gonopodium used to deliver sperm to females (Van Tienhoven, 1983). The size and shape of the gonopodium reveals information about evolution and classification of the Poeciliidae. The coelacanth *Latimeria chalumnae* is ovoviviparous. There is internal fertilization, and the fetuses are retained within the mother until they have grown large enough to fend for themselves. There is no obvious copulatory organ in the male, so much remains to understand about reproduction in coelacanths. The gestation period has been estimated to be around 13 months.

The Mozambique tilapia, *Oreochromis mossambicus*, native to Africa, is a widely aquacultured species that is also highly invasive in some countries. Males construct nests in sparse vegetated areas of lakes where fertilization of the eggs takes place (Bruton and Bolt, 1975). Several different females may lay eggs in the nest. Males are generally aggressive and ritualistic during reproductive season. Once fertilized, the female takes the eggs into her mouth and broods them until hatching in about 3–5 days.

Diversity in Mating Systems

Promiscuity is common in Osteichthyes. The eggs of a female are potentially fertilized by several males, with minimal selection of partners. Alternatively, in some species males may potentially fertilize the eggs of several females. Breeding aggregations of promiscuous spawners can make some fish species particularly vulnerable to fishing. The pelagic Atlantic herring, *Clupea harengus harengus* is commercially important and one of the most abundant fish species on earth, gathering in large schools. The species migrates for feeding, spawning, and over-wintering purposes and are found on both sides of the Atlantic.

Polygamy generally refers to a mating system in which one sex mates with several con-specific partners, but with the same mate at each spawning. The Mozambique tilapia is an example of a polygynous species where males mate with several females, but each female spawns with only one male. Male tilapia perform site selection and nest building (Bruton and Bolt, 1975). They form dense aggregations of territories in which they dig and defend nest pits (Bruton and Bolt, 1975). Ripe females visit the breeding arenas and when male courtship is successful, enter the pits to spawn. The size of male spawning pits is positively correlated with male status (Oliveira and Canário, 2000), and may serve to attract desirable females for spawning. Female Mozambique tilapia may gain a direct benefit from choosing to spawn with a male with a larger pit, which could be associated with a reduced likelihood of interference and cannibalism (Oliveira and Canário, 2000).

Females in polyandrous species mate with several males, but each male spawns with only a single female. The guppy *Poecilia reticulata* is a highly polyandrous live-bearing fish in which males transfer sperm internally to females via consensual and forced mating. Guppies exhibit some of the highest recorded rates of multiple paternity in any vertebrate (Neff et al., 2008).

A form of promiscuity with the possibility of mate selection is polygynandry (Wootton and Smith, 2015). A male will spawn with several females and a female with several males over the course of a breeding season, but with mate choice operating. The European bitterling *Rhodeus sericeus* is a freshwater polygynandrous cyprinid with an unusual relationship with mussels (Smith et al., 2004). During the spawning season, males develop bright breeding colors and defend territories around mussels. Female bitterlings develop long ovipositors that they use to place their eggs onto the gills of a mussel through the mussel's exhalant siphon. Males fertilize the eggs by releasing sperm into the inhalant siphon of the mussel, so that water filtered by the mussel carries the sperm to the eggs. Developing embryos live inside the mussel for 1 month as they develop into swimming larvae (Smith et al., 2004).

In monogamy, a single male and female form a mating pair and show some degree of bonding with the mate (Wootton and Smith, 2015). This type of mating system is not common in bony fishes but is associated with species in which parental care follows the fertilization of eggs. The pair bond may be long-lasting or more temporary, only persisting for a single breeding attempt. The convict cichlid, *Amatitlania nigrofasciata*, is a monogamous South American cichlid, perhaps not typical of many other cichlids that exhibit diverse breeding behaviors.

Secondary Sexual Characteristics

In many fishes, the sexes differ in appearance. This could be permanent or a sex hormone-dependent, temporary difference only evident at the breeding season. Female and male Atlantic herring resemble each other and are therefore called monomorphic. Atlantic herring are polygynandrous and aggregate into massive schools in the late summer and early fall. In the western Atlantic, they move into coastal waters at various locations in the Gulf of Maine and offshore banks of Nova Scotia to spawn. An example of permanent sexual dimorphic fish is the Siamese fighting fish, *Betta splendens*, a type of gourami. The male is very colorful, with long, elegant fins. He builds a bubble-nest which is aggressively guarded. The male *Betta* is well-known to aquarists because of the dramatic fin displays. The female is less colorful with smaller fins. Many fish only display sexual dimorphism in the breeding periods; for example, male cyprinids such as the common goldfish, *Carassius auratus*, develop breeding tubercles on the pectoral fins and the operculum as sex hormone (androgens) levels increase for spring spawning. Breeding tubercles may function to maintain body contact between the sexes during spawning; in the defense of nests and territories; in the stimulation of females in courtship; and in some forms, perhaps in sex and species recognition. Breeding tubercles are found in 15 families of 4 orders; Salmoniformes, Gonorhynchiformes, Cypriniformes, and Perciformes.

Spawning Site Preparation

Many fish do not exhibit any spawning site preparation. For example, in the Eurasian minnow, *Phoxinus phoxinus*, males and females form schools separately and arrive on the spawning site at different times. They spawn over clean gravel areas in flowing water or on wave-washed shores of lakes. Females lay sticky eggs deep into clean gravel (Kottelat and Freyhof, 2007). Atlantic salmon, *Salmo salar* are a commercially important species with a complex life cycle in the wild. They breed in freshwater but grow and live in the ocean. They return to home rivers, entering freshwater between April and November. In late fall the wild Atlantic salmon spawn. The female digs a 10–30 cm deep nest called a redd in the gravel bottom of the stream. Her eggs and the milt from an adult male are released into the redd, the eggs are fertilized, the gravel replaced with additional tail thrusts. The classic example of complex site preparation is nest-building and defense by the three-spined sticklebacks *Gasterosteus aculeatus* (Fig. 2). In the breeding season, the male with the bright red throat collects grasses and constructs a nest by gluing together the plant material with the specialized protein spiggin secreted from the kidney under the control of androgenic testicular hormones.

Parental Care

Most Osteichthyes do not exhibit parental care, and abandon fertilized eggs once spawning is completed. The African lungfish *Protopterus annectens* spawn in the swamps during the wet season; they build nests in which the eggs, white in color and about

Fig. 2 Classic illustration of three-spined stickleback breeding by A.F. Lyndon. This is taken from *British Fresh Water Fishes*, Volume 1, December 31, 1878 by Houghton, William, 1828–95, Lydon, Alexander Francis, 1836–1917 and is in the public domain.

4 mm diameter, are laid; the young are cared for by the males. The larvae hatch in 8 days, and leave the nest in twenty days. The male three-spined stickleback serves as a good example of paternal care of eggs in a nest (Fig. 2). In maternal care, the female takes care of the developing eggs. The female Mozambique tilapia, *Oreochromis mossambicus* takes eggs into her mouth and broods them until hatching, then continues to mouth-brood the fry until they are approximately 2–3 weeks old. A second form of maternal care is seen in viviparous species in which the eggs are fertilized and develop within the ovaries of the female. The classic examples of this are the viviparous live-bearing species in the family Poeciliidae. These are the tooth-carps, and include well-known aquarium fish such as the Common guppy, *Poecilia reticulata*, sailfin molly, *Poecilia latipinna*, and green swordtail *Xiphophorus hellerii*. Convict cichlid couples on the other hand, jointly care for their eggs, newly-hatched free embryos and free-swimming juveniles for four to six weeks (Wisenden, 1995). Eggs are laid on the ceiling of small caves which the pair have previously prepared by excavating sand from under large stones. Both parents guard the young, aggressively chasing away potential brood predators. The daffodil cichlid *Neolamprologus pulcher* is a cooperatively breeding cichlid endemic to Lake Tanganyika in East Africa. They live in social groups consisting of a dominant breeding pair and up to 14 related and unrelated helpers (Balshine *et al.*, 2001). Helpers clean and fan eggs in the breeding shelter and help to defend the territory and other group members against predators and intruding conspecifics.

Conclusions

Modes of reproduction are highly diverse in fish. Given the number of species it is difficult to classify reproductive patterns according to phylogeny. What is clear, however, is that both external and internal fertilization, complex sexual behaviors, and parental care have all evolved very early in the vertebrates, given the appearance of the first fishes approximately 400 million years ago. Much remains to be discovered in the majority of fish, and especially non-teleostean species.

Overview of Amphibian Reproduction

Sarah K Woodley, Duquesne University, Pittsburgh, PA, United States

Introduction

Some 360 million years ago, the ancestors of modern amphibians hauled themselves out of the water to colonize the land, escaping from aquatic threats and discovering new prospects. Early amphibians likely had a biphasic lifestyle: hatching and developing in water as a larval form with gills, but transforming into a terrestrial life form after undergoing a dramatic morphological and physiological reshaping called metamorphosis. The biphasic lifestyle is widespread in modern amphibians, but the innovative strategies used by amphibians to reproduce at the nexus of land and water are largely underappreciated. In fact, amphibians have the greatest diversity of reproductive strategies of all vertebrates, exploiting both aquatic and terrestrial niches to reproduce and pass on their genes. With these evolutionary innovations, amphibians are found in almost every habitat of the world.

To date, more than 7700 species of amphibians exist, distributed among anurans (frogs and toads, ~6800 species), urodeles (salamanders, ~700 species) and the secretive limbless gymnophionans (caecilians, ~200 species) (see Relevant Website section; Crump, 2009). Although anurans are found throughout the world, most salamanders live in temperate zones, with the exception of one large lineage of salamanders found in parts of Mexico and Central and South America (neotropics). In contrast, caecilians are mostly found in tropical areas. Members of the three orders of amphibians are united by a reliance on water. With their thin skin and shell-less eggs, they are prone to water loss and desiccation. As cool-blooded animals that prefer cool temperatures, amphibians have a low metabolic rate and assimilated energy supports growth and reproduction rather than thermoregulation. Despite their low metabolic rate, oxygen availability can be limiting and impair development.

The following overview of amphibian reproduction offers a taste of the rich diversity of modes while highlighting common themes. For more information on many of the themes and examples described in this overview, the reader is referred to the following reviews: Duellman and Trueb (1994), Crump (1996), Wake (1999), Jamieson and Exbrayat (2006), Wells (2007), Petranks (2010), Woodley (2010), Wake (2015), Woodley (2015). Reproduction encompasses the production of eggs and sperm, fertilization, and development, is shaped by physiological and environmental factors, and involves complex male-female and parent-offspring behavioral interactions. Despite their unique amphibian features, study of amphibians can teach us much about reproduction in other vertebrates, including humans, because of conserved foundational principles of vertebrate reproduction.

A discussion of amphibian reproduction is also relevant for conservation of biodiversity. Many fascinating reproductive modes are found in species that are dwindling or extinct. As an infamous example, in the now extinct gastric brooding frog (*Rheobatrachus*), the mother swallowed her fertilized eggs and incubated them in her stomach until they hopped from her mouth as froglets. Gastric brooding frogs are now extinct, likely due to habitat destruction or disease. Disease is particularly disturbing, impacting amphibians across the world, even those in relatively pristine habitats. The latest threat is the chytrid fungus (*Batrachochytrium salamandrivorans*), which is killing the charismatic fire salamanders of Europe and will likely reach North America in the near future, with similar consequences. Thus, an additional incentive to study amphibian reproduction is for captive breeding, as scientists desperately seek to preserve amphibians from extinction. Conversely, some amphibians like cane toads (*Rhinella marina*), after being introduced across the world to control pests, are now expanding their ranges and threatening native species. In this case, their reproduction is studied to control their expansion and to better understand properties of invasive species.

Proximate Control of Reproduction

Amphibian reproduction is shaped by the interplay of genetic and environmental factors. Environmental factors signal when it is suitable to reproduce. Moisture is necessary for hydration of adults and eggs, and temperatures must be sufficiently warm to support physiological processes like making sperm and eggs, sustaining reproductive behaviors, or feeding to gain energy for reproduction. Thus in temperate zones, warming temperatures and rainfall are key proximate signals of suitable conditions for reproduction. In species living in subtropical or tropical areas where temperatures are warm year round, rainfall and humidity are the primary cues. Additional important signals include food availability and social stimuli like the chorusing of male frogs at the breeding site.

Environmental cues are perceived by the nervous system which then activates the endocrine system, specifically the hypothalamic-pituitary-gonadal axis (Vu and Trudeau, 2016). As a conserved vertebrate mechanism, activation of the hypothalamic-pituitary-gonadal axis regulates sperm and egg production, and produces elevated levels of reproductive hormones like androgens and estrogens from the gonads. The reproductive hormones act throughout the body to ensure that sperm and egg production is synchronized with morphological and behavioral traits crucial for reproduction. As a few examples, in female red-bellied newts (*Cynops pyrrhogaster*), prolactin and estrogen stimulate the production of a pheromone which travels through the water to attract males for mating. In female marsupial frogs (*Gastrotheca riobambae*), gonadal hormones stimulate the seasonal development of specialized skin pouches that house developing offspring. In male anurans, androgens stimulate the enlargement

of horny thumb pads that help males grasp females during mating. Androgens also act on the vocal cords of male anurans to facilitate calling behavior that attracts females or warns off rival males. In the brain, reproductive hormones regulate expression of behaviors like searching for and finding potential mating partners, courtship, mating, and parental behaviors. The gonadal hormones tend to regulate behavior in a permissive manner, with additional hormones like prolactin, vasotocin, and corticosterone modulating more minute-to-minute changes in behavioral expression. Understanding of the proximate mechanisms underlying amphibian reproduction derives from a few common species of anurans and urodeles, typically found in temperate zones. Less is known about neuroendocrine mechanisms in neotropical or tropical amphibians, or in caecilians.

Reproductive Strategies and Seasonal Patterns

Amphibian strategies for maximizing their ability to produce offspring that survive to adulthood vary, and amphibians are quite flexible in their ability to reproduce given suitable conditions. Reproductive lifespan and fecundity varies across amphibian species. At one end of the spectrum, the aquatic European cave salamander (*Proteus anguinus*) lives an average of 60 years and breeds every 13 years laying less than 100 eggs at a time (Voituron *et al.*, 2011). At the other extreme, the gladiator treefrog (*Hysiboas rosenbergi*) in Panama reproduces in the rainy season following hatching, laying up to 6 clutches, each with thousands of eggs, and does not survive to the next rainy season. Most species have aquatic or terrestrial eggs/larvae, although some species, especially caecilians, are viviparous, whereby fertilized eggs develop inside the mother's oviducts, emerging as larvae or juveniles with the adult morphology.

The geography of an area sets the environmental parameters and thereby shapes the timing of reproduction. However, amphibians are excellent at coping with constrained environmental conditions, leading to many different reproductive modes in similar geographic zones. The following discussion describes amphibian reproduction according to terrestrial versus aquatic lifestyles, but note that the rich diversity of amphibian reproduction defies easy categorization.

Terrestrial Adults With Aquatic Breeding

The biphasic life cycle of terrestrial (including amphibians specialized for life in trees or burrows) adults that return to water to breed is quite successful. It was presumably the ancestral amphibian mode and is still a predominant life cycle in amphibians. Because the biphasic life cycle is less constrained by rainfall and humidity, especially in species that breed in permanent water, it has a wide geographic distribution.

In amphibians living in temperate zones, warm spring temperatures stimulate increases in gonad size and hormone levels, priming the system for reproduction when rainfall and humidity are also available. In many temperate zone amphibians, breeding occurs mostly in the spring and summer months wherever water is found, such as in ponds, streams, and wetlands. In some cases, reproduction is brief, concentrated in a few weeks of spring, when snow is melting and rain falls, creating temporary, predator-free sources of water for breeding. An example is the explosive breeding of spotted salamanders (*Ambystoma maculatum*) in eastern North America and Canada, where warm spring rains trigger the mass migration of salamanders from terrestrial burrows to vernal ponds for frenzied breeding over a few nights. Adults return to land to feed for the rest of the summer, leaving aquatic eggs to hatch into larvae that metamorphose into terrestrial juveniles a few weeks later before the pond dries up. Explosive breeding can also occur in desert-adapted amphibians, where late summer rainfall triggers the emergence of species like the desert spadefoot toad (*Scaphiopus*) from moist underground refuges to breed in ephemeral ponds or puddles. In cases where breeding areas remain wet throughout the summer, or in permanently aquatic habitats like streams, breeding can be prolonged, with multiple cycles of breeding. For example, wood frogs (*Lithobates sylvaticus*), an early spring breeder with aquatic eggs and tadpoles, will breed repeatedly if ponds and wetlands stay wet into the summer.

In warm and wet tropical rainforests where productivity and carrying capacity is high, frogs and caecilians are especially diverse. In the tropics, hormones appear to be continuously elevated and egg and sperm production is ongoing. Breeding can occur year-round in permanently aquatic areas or as a function of rainfall and humidity. In some species of caecilians, females lay eggs near water and hatchlings wriggle into adjacent water. Anurans of the humid Atlantic Forest of Brazil exemplify the diverse reproductive strategies of tropical amphibians, where terrestrial adults have adapted to breed in a wide range of watery sites including streams, ponds, puddles, nooks in plants, and even water filled basins or moist foam nests (Haddad and Prado, 2005).

Development requires oxygen, and in tropical areas with warm temperatures, oxygen content in the water decreases. Thus, many amphibians (in both tropical and temperate zones) lay eggs in well oxygenated streams, avoiding oxygen-poor sites like swamps. Other adaptations to ensure adequate oxygen include laying small eggs with a high surface to volume ratio to maximize oxygen diffusion, placing eggs on the surface of the water in partial contact with air, laying eggs in constructed foam nests or laying eggs out of water all together (see next section on terrestrial egg-laying).

Terrestrial Adults With Terrestrial Breeding

In the biphasic life cycle, reproduction is heavily constrained by availability of water because eggs and/or larvae are aquatic. Many amphibian species, however, have found ways to breed in the absence of water to avoid aquatic predators and competitors and to

exploit new niches. Although liberation from water provides new opportunities, the relatively dry, terrestrial environment can be harsh on developing young. Some traits associated with terrestrial development include larger egg size to minimize water loss, smaller clutch size, and parental care to keep terrestrial eggs or larvae hydrated and nourished. Terrestrial life styles are often found in warm humid tropics, but are found in more temperate climates as well.

A common terrestrial strategy is “direct development”, which is found in both temperate and tropical climates (Wake, 2003). Here, eggs are laid on land and development skips the free-living larval stage. At hatching, the offspring look like miniature adults, ready for a terrestrial lifestyle. With direct development, egg production is less constrained by annual cycles of rainfall, although moist conditions are still required to prevent desiccation of clutches and to allow adults to forage to gain energy for growth and reproduction. Virtually all species in the large family of eleutherodactylid frogs have direct development. An example is the coqui frog, (*Eleutherodactylus coqui*). Native to the tropical forests of Puerto Rico, the coqui frogs lay egg clutches of a few dozen eggs in plant fronds or in curled leaves, where they are cared for by the father. Within a few weeks, eggs hatch into froglets, which become sexually mature after a few months, with adults breeding every few weeks. Continuous reproduction combined with direct development has made coquis into a highly invasive species.

Direct development is also found in all neotropical plethodontid salamanders, the largest family of salamanders. Neotropical salamanders are found in cool, mid-elevation cloud forests that have wet and dry seasons. Study of the neotropical salamander (*Bolitoglossa rostrata*), found that adult males are capable of mating year-round, having sperm and pheromone-producing glands at all times. Females, however, lay eggs in moist refugia once a year at the beginning of dry season. Females attend to the clutch until the start of the wet season when the young hatch out fully formed, ready for a terrestrial life style (Houck, 1977). This illustrates that even in warm climates, reproduction may be highly seasonal.

Another strategy to reproduce with minimal water is to bear live young (viviparity) (Wake, 2003, 2015). In some subspecies of fire salamanders (*Salamandra salamandra*) living in cool montane habitats, fertilized eggs develop inside the mother's oviduct. Once the young's yolk is depleted, they feed on unfertilized eggs and oviductal secretions. After several months of gestation, fully metamorphosed juveniles are born.

Although live bearing is very rare in anurans and salamanders, it is a common strategy in caecilians. It has evolved independently four different times and is found in 75% of the caecilian species. Typically, the entire developmental process including fertilization, hatching of eggs, and metamorphosis occurs within the oviducts with fully-formed young emerging from the female. Interestingly, this form of viviparity (or live-bearing) is not restricted to species with terrestrial lifestyles; it also occurs in aquatic species of caecilians.

Aquatic Adults With Aquatic Breeding

Despite the diverse adaptations that emancipate amphibians from water, many amphibian species remain aquatic their entire lives. An example is the African clawed frog (*Xenopus laevis*), where tadpoles metamorphose into aquatic juvenile frogs. Another example is the South American caecilian, (*Typhlonectes*), which is aquatic/semi-aquatic, sheltering in submersed holes along muddy banks, giving birth to live young that are also aquatic. Aquatic lifestyles are also evident in the larger types of salamanders, like the proteids, sirenids, and cryptobranchids. Interestingly, aquatic lifestyles in salamanders are often associated with prolonged larval development. At its most extreme is the occurrence of paedomorphosis. Paedomorphosis occurs when gonads mature in the larval body form, and sexually reproducing adults retain larval traits like gills. The large blood-filled feathery gills found in adult paedomorphic mudpuppies, sirenids, and axolotls (*Ambystoma mexicanum*) are striking in appearance.

Reproductive Behaviors

For successful reproduction, males and females must find each other and mate. In addition, in some species, offspring survival requires parental care. A rich array of mating and parental care behaviors is displayed across the three orders of amphibians. The type of reproductive behaviors is somewhat related to the mode of fertilization and whether breeding is terrestrial or aquatic.

Mating

Anurans

In almost all anurans, fertilization occurs externally. While in a copulatory embrace called amplexus, the male releases sperm while the female lays her eggs, typically into water. This method of fertilization shapes male strategies for siring offspring. Male anurans typically congregate around breeding sites and advertise their presence by calling, using their vocal sacs for amplification. In species where mating occurs explosively over a short period of time, males directly compete with other males for access to females, often aggressively wrestling (scramble competition), and larger males sire the most offspring. In species where mating occurs over a more prolonged period, males may adopt alternative tactics for siring offspring. For example, within a species, some males may defend a territory while others patrol the periphery to find receptive females. In such systems, a female can choose the male who will fertilize her eggs. In some cases, females may choose a male based his ability to provide and defend resources like feeding or oviposition sites. In other cases, it is not clear what males might be contributing to the reproductive effort other than sperm.

In a very few species, males inseminate females and fertilization is internal. For example, male tailed frogs (*Ascaphus truei*) possess a cloacal extension, or “tail” that is inserted into the female’s cloaca, which is helpful for mating in fast-moving mountain streams.

Salamanders

In salamanders, fertilization in several families is external (Houck and Arnold, 2003). For example, hellbender (*Cryptobranchus alleganiensis*) males dig a shallow nest under rocks in clear streams. Females enter the male’s nest, oviposit and leave. Males release sperm over the eggs and then tend to the eggs and developing larvae for several weeks. The majority of salamander species, however, have internal fertilization. Salamanders lack intromittant organs and transfer sperm to females with a spermatophore. The spermatophore, a major evolutionary innovation, is a gelatinous mass, deposited on the substrate, with sperm on the top. A female will step over the spermatophore and collect the sperm into her cloaca. The sperm is stored in a special cloacal chamber until eggs are laid, at which point they are fertilized. The use of a spermatophore has important implications: mating and egg-laying can be separated in time, and females can mate with multiple males. In Ocoee salamanders (*Desmognathus ocoee*), females mate with multiple males from fall to spring and lay eggs during the summer months. This allows greater flexibility because environmental conditions suitable for mating are not always suitable for egg laying and development.

Salamanders do not vocalize, instead relying on chemical cues to find members of the opposite sex and coordinate mating interactions (Woodley, 2014). Furthermore, use of a spermatophore to transfer sperm involves complex courtship behaviors and pheromonal communication in multiple salamander families. All plethodontid salamanders express a tail-straddling behavior which has been evolutionarily static for millions of years and functions to coordinate male and females for successful sperm transfer. Similarly, male rough-skinned newts (*Taricha granulosa*) clasp females for hours both before and after spermatophore deposition and sperm transfer, presumably to shape female receptivity. During these courtship interactions, males secrete peptide and proteinaceous pheromones that induce females to mate more readily. In newts, the pheromones are simple peptides (sodefrin in red-bellied newts (*Cynops pyrrhogaster*)) while they are complex mixtures of different molecules and isoforms in plethodontid salamanders (e.g. red-legged salamanders (*Plethodon shermani*)).

Caecilians

Almost all caecilians have internal fertilization which they achieve with copulatory organ called a phallodeum which is inserted in the female’s cloaca during mating. They have well developed olfactory senses so chemical communication is likely important. Unfortunately, very little is known about their mating behavior (Jamieson and Exbrayat, 2006).

Parental Care

After mating, most amphibians lay their eggs and leave with no further care for offspring (Crump, 1996). However, parental care has evolved in multiple lineages in all three amphibian orders. Parental care is the investment in offspring after fertilization, and its main function is to protect and/or nourish offspring. Parental care is more common in species with terrestrial breeding as a way to enhance offspring survival in a potentially harsh terrestrial environment, but it is also found in aquatic habitats. Parental care includes nest construction; egg or larval attendance; egg or larval transport or brooding; larval feeding; and internal gestation in the female. Parental care can be exhibited by the mother, father, or both. External fertilization is often associated with male parental care, and internal fertilization with female parental care, although there are exceptions.

Anurans

Parental care is relatively rare in anurans, present in about 10% of species. Species may construct nests either on land or water. Foam nests are common and can protect aquatic eggs from dangerous water currents and terrestrial eggs from dehydration. In some species, parents dig out water-filled cavities or basins for eggs and larvae. In some terrestrial breeders, females lay eggs in leaves that are sealed into a protective shelter using oviductal secretions. Nests alone may not be sufficient to enhance offspring survival, and parents may attend eggs or larvae to protect them from predators, microbial infections, or desiccation. If eggs and larvae develop in nutrient poor sites such as leaf axils or tree holes, feeding is required. Mimic poison frogs (*Ranitomeya imitator*) from Peru breed in small pools in the folds of tree leaves, presumably to avoid predators. Males monitor the eggs, and females periodically deposit unfertilized eggs for the offspring feed on. Notably, the male-female pair is monogamous, one of the rare examples of monogamy in an amphibian (Brown *et al.*, 2008).

Another interesting form of parental care is carrying eggs/larvae to protect, nourish, or transport them. Varied adaptations support these functions. In aquatic pipid frogs, eggs develop while embedded in back of the female, either hatching into tadpoles or into froglets, depending on the species. In Darwin’s frog (*Rhinoderma darwinii*), the male attends the eggs until they are about to hatch at which point he laps them into his vocal sac. The young develop within the vocal sac, ingesting yolk or paternal secretions from the vocal sac lining. Finally, in the midwife toads of Europe and North America (*Alytes*), males carry strands of fertilized eggs entwined around their hind legs for about 1 month. At hatching, the clutch is deposited into a pool. Similar forms of parental care are found in fully terrestrial species, such as in the Australian pouched frog (*Assa darlingtoni*). Here, females attend eggs but males brood the tadpoles which slither into lateral pouches remaining there until metamorphosis, which may be several months later.

Finally, out of the more than 6800 species of anurans, only a few give birth to live young. In the African genera of *Nectrophrynoides* and *Nimbaphrynoides*, fertilized eggs develop within the oviduct and females give birth to froglets. In the fanged frog (*Limnonectes larvaepartus*) from Indonesia, females give birth to tadpoles in puddles along streams (Iskandar *et al.*, 2014). The rarity of viviparity in anurans reflects that only 17 anuran species have internal fertilization.

Salamanders

Salamander parental care is found in several families, but is less varied than in anurans. Usually restricted to egg attendance, its main functions are probably aeration of aquatic eggs, moistening of terrestrial eggs, and protection against egg predators and fungal infection. Male parental care is common in species with external fertilization. For example, the aquatic Japanese giant salamander (*Andrias japonicus*), like its relative the hellbender, cares for clutches of eggs. Behaviors include eating dead or infected eggs and tail-fanning. Asiatic salamanders in the hynobiid family have a biphasic life cycle where adults return to water to breed. Fertilization is external and males guard egg clutches.

Female parental care is very common in salamander species with direct development, such as those in the plethodontid family. Here, fertilization is internal, occurs at the time of oviposition, and usually occurs days to months after mating. Females stay with terrestrial eggs until they hatch. Behaviors include agitating the eggs, eating infected eggs, and moving through eggs. Egg attendance may function to inoculate clutches with antimicrobial secretions, bacteria, or bacterial metabolites from the mother's skin to protect eggs against fungal disease. Egg attendance can last several weeks to months, during which the mother does not eat. A rare case of alloparental care is found in the four-toed salamander (*Hemidactylium scutatum*), where multiple females may deposit eggs into the same nest, but only a single female attends the eggs.

Caecilians

Parental care is widespread in caecilians. In many egg-laying species, the mother coils around the eggs while they develop. An unusual behavior called maternal dermatophagy is found in several groups of caecilians where hatchlings quickly gain weight by using specialized fetal teeth to eat the outer layer of the mother's skin, which hypertrophies to become nutrient-rich (Wilkinson *et al.*, 2013). Maternal dermatophagy, with its associated specialized fetal teeth, may have been the antecedent to the evolution of caecilian viviparity, in which embryos survive within the oviduct by eating other eggs or by ingesting nutrients obtained by scraping the oviductal walls with specialized teeth.

Conclusions

Despite physiological constraints related to hydration, oxygen availability, and temperature, amphibians have evolved ingenious strategies for exploiting the water/land interface, especially in the tropics where suitable microniches are abundant and productivity is high. These innovations have occurred while adhering to conserved vertebrate mechanisms of gamete production and neuroendocrine control. Indeed, amphibians have the greatest diversity of reproductive strategies of the vertebrate classes. In addition to the marvelous species diversity, there is also substantial plasticity within species, providing additional opportunities for animals to breed and pass on their genes. Most work on the neuroendocrine control of amphibian reproduction is restricted to a few species, but new species are discovered every year offering new opportunities to test hypotheses about the physiological mechanisms and evolutionary forces that shape amphibian reproduction. However, the discovery of new species is tempered by the increasing loss of amphibian species, and this article may provide readers with a better appreciation for amphibian biodiversity and the importance of studying amphibian reproduction.

Glossary

Amniotic egg Terrestrial egg of reptiles, birds, mammals, and their extinct relatives.

Oviparity The reproductive pattern in which females lay eggs that complete their development and hatch in the external environment.

Parthenogenesis Asexual reproduction, in which females produce genetically similar female offspring without fertilization.

Sex determination pattern The mechanism affecting whether an embryo develops as a female or a male. Sex determination can be genetic or be affected by developmental temperature.

Squamates The scaly reptiles, i.e., lizards and snakes.

Viviparity The reproductive pattern in which embryos complete their development inside the female reproductive tract before being born.

Introduction

Living (non-avian) reptiles traditionally are classified in four orders: Squamata (lizards and snakes: with >10,000 species); Rhynchocephalia (the tuatara *Sphenodon punctatus*); Chelonia (turtles: 346 species); and Crocodilia (alligators, crocodiles, and gharials: 25 species). The tuatara is of special evolutionary interest as a lepidosaurian relict that shared a common Mesozoic ancestry with squamates. Extinct reptiles of the Paleozoic and Mesozoic include many other groups, such as the aquatic ichthyosaurs, plesiosaurs, and mesosaurs; winged pterosaurs; and dinosaurs (ornithischians and saurischians, including birds). Despite their enormous diversity, reptiles share several reproductive features inherited from their distant Paleozoic ancestors. Among these features are internal fertilization; a terrestrial “amniotic” egg; and production of fully-developed offspring. Reptiles contrast with most amphibians, which lay aquatic eggs that are fertilized externally, from which hatch aquatic larvae that must undergo metamorphosis to attain adult body form.

Despite their shared features, extant reptiles are highly diverse in terms of reproductive parameters. Any brief account can only touch upon the complexity and diversity of reptilian attributes. Readers can refer to the bibliography for more information.

Overview of Reptilian Reproduction

Overall structure of the male reproductive system is similar (but not identical) throughout reptiles (Pough *et al.*, 2016). Sperm are produced in the testes, transported by the ductus deferens, and either stored in the ductus or the epididymis. In male squamates, secretions of the kidney contribute to the seminal fluid; their functions are not well understood, although in anole lizards, such secretions may nurture the sperm. In crocodilians and turtles, the intromittent organ consists of a single vascular erectile body that protrudes from the cloaca. Squamates have paired hemipenes, each with a groove to carry sperm and a head ornamented with papillae and/or spines that fix it in place during copulation. An intromittent organ is lacking in tuatara (as in most birds) and copulation occurs through apposition of the male and female cloacae. A recent analysis of *Sphenodon* embryogeny revealed a phallic precursor, suggesting that absence of the intromittent organ represents an evolutionary loss (Sanger *et al.*, 2015).

In female reptiles, ovarian oocytes accumulate yolk, are ovulated, and eggs then are fertilized in the anterior oviduct (Ramírez-Pinilla *et al.*, 2015). Oviducts are paired structures in most squamates; however some snakes and lizards retain only one, as an adaptation to elongated body form. The oviduct consists of an infundibulum, where fertilization occurs; a posterior infundibulum which (in turtles and crocodilians) contains glands that secrete albumen; a uterus, which deposits the shell; and a posterior “non-glandular uterus” which expels the egg at oviposition (Blackburn, 1998; Cree, 2015). The oviductal epithelium and glands undergo changes in concert with reproductive cycles, under the influence of steroid hormones.

The extent of embryonic development that occurs before the egg is laid varies markedly by group (Pough *et al.*, 2016). In turtles, crocodilians, and the tuatara, eggs are laid in a very early developmental stage. In fact, in turtles, oviductal eggs undergo stasis prior to oviposition to prevent development beyond the gastrula stage. However, in oviparous squamates, eggs typically are laid in the limb bud stage. In viviparous (live-bearing) lizards and snakes, embryos complete their development in the uterine oviduct, and are born as fully-developed neonates.

Specializations of the amniotic egg (Table 1) have allowed reptiles to reproduce entirely on land (Pough *et al.*, 2016) and in fact, require terrestrial reproduction (except in viviparous forms). These specializations include a protective eggshell plus fetal (“extraembryonic”) membranes that sustain the developing embryo. Eggs of crocodilians and turtles (but not squamates or

Table 1 Features of the amniotic egg of reptiles.

Feature	Function
Eggshell	Mechanical & hydric protection; protection from microbes & predators
Chorioallantois	Respiratory gas exchange; calcium uptake from the eggshell
Amnion	Mechanical protection of the embryo
Albumen ^a	Water & protein provision
Large yolk	Production of fully-developed hatchlings
Yolk sac	Yolk storage & digestion
Fetal membranes ^b	Water uptake

^aAbsent in squamates and probably the tuatara.^bMechanism not known.

tuataras) also are supplied with albumen, which provides water and protein. Reptilian eggs can be buried in the ground, hidden in debris or in cavities in rocks or trees, or laid in decaying vegetation. Crocodilians lay eggs in above-ground nests. Once deposited, reptilian eggs exchange respiratory gases and (typically) absorb water across their eggshells. Although eggshells of most reptiles are flexible, many turtles and most gekkos have hard, calcareous shells that provide greater mechanical protection but are less permeable to water.

Reproductive Features

Sex Determination

Reptiles are highly diverse in mechanisms affecting sexual development of embryos (Pough *et al.*, 2016). In temperature – dependent sex determination (TSD), egg temperature during development affects whether the embryo develops as a male or female. TSD occurs in turtles, crocodilians, most lizards, and the tuatara. Species vary as to whether females result from eggs incubated at (a) relatively warmer temperatures (some turtles); (b) cooler temperatures (*Sphenodon*); (c) or at temperature extremes (crocodilians and some turtles). In each instance, males result from eggs incubated at the alternative temperatures. All three patterns are found among lizards.

In genetic sex determination (GSD), differentiation depends on sex chromosomes, and can show male- heterogamety (the XY system, as in mammals) or female heterogamety (the ZW system, as in birds) (Vitt and Caldwell, 2014). Snakes exhibit the ZW system; however, the Burmese python (*Python bivittatus*) and the Central American boa (*Boa imperator*) have an XX/XY system. Lizard species can have either form of GSD. However, in the Australian bearded dragon (*Pogona vitticeps*), chromosomes and incubation temperature affect phenotypic sex.

Much research has focused on the mechanisms, adaptive significance, and evolution of the patterns of sex determination. Theoretically, TSD should be favored evolutionarily when the optimal developmental temperature differs between males and females. The Australian agamid lizard *Amphibolurus muricatus* conforms to this prediction. Due to its TSD, reproduction in the spring produces proportionately more female offspring. These young lizards can grow and overwinter at larger body sizes than females from eggs laid later in the year. Because adult female size correlates with clutch size, TSD therefore has evolutionary advantages in this species. TSD appears to be ancestral for reptiles, but multiple evolutionary transformations between mechanisms clearly have occurred in reptilian history (Vitt and Caldwell, 2014). Currently, a major concern is that anthropogenic climate change puts many species with TSD at serious risk of extinction (Cree, 2014).

Clutch Sizes

In most reptile species, clutch size can vary widely between individuals, age classes, geographical location, and from year to year (Vitt and Caldwell, 2014; Mesquita *et al.*, 2016). Nevertheless, phylogenetic patterns are evident. In turtles, clutch size typically is about 1–6 eggs; however, clutches of up to 150 eggs have been reported in species with very large individuals. Clutch sizes in crocodilians commonly range from 6 to 60 eggs, with the largest figures being representative of the Nile crocodile. In tuataras, average clutch size varies by population from 9.4 eggs on Stephens Island to 5.9 eggs on some smaller islands. A few lizard species show invariant, small clutches. Among them are anole lizards (in which the female lays an egg every 7–10 days), and gekkos that oviposit clutches of 1–2 eggs. Some oviparous chameleons lie at the opposite extreme among lizards, with mean clutch sizes of 50 eggs, and clutches of up to nearly 100 eggs in individual cases. Oviparous snakes show a similar range, with average brood sizes that range from 3 (e.g., the crown snake, *Tantilla coronata*) to 46 (certain *Python*). Within and between squamate species, clutch size often correlates with female size. Clutch size also can vary in a species according to resource availability. In some species, such as the lizard *Lacerta agilis*, a tradeoff between clutch size and egg size has been documented. Such a tradeoff also is evident in comparisons of closely related species, and accounts for some of the broad differences apparent at higher taxonomic levels.

As for viviparous squamates, very small litters (1–3 offspring) characterize live-bearing gekkoes and cordylids, whereas the largest reported litters are in chameleons (up to 50 offspring) and vipers (80–100 offspring). Phylogenetic variation tends to obscure broad

differences that might be attributable to reproductive mode, although such differences sometimes are apparent in comparisons of closely related species (Stewart and Blackburn, 2015).

In lizards, measures of relative clutch mass ("RCM," the ratio of clutch to body mass) have been shown to relate to modes of foraging as well as predator escape (Vitt and Caldwell, 2014). The RCM in streamlined, active foragers tends to be much smaller than in lizards (such as horned lizards and chameleons) that "sit-and-wait" for their insect prey. Burden of the clutch has been shown to affect maternal locomotion. For example, in the side-blotched lizard *Uta stansburiana*, experimental reduction of the clutch by 30% produces higher levels of endurance and survival in gravid females. In the European lizard *Zootoca vivipara*, females with heavier litters weigh less after birth than other females. Thus, large litters can be costly to females in ways that may affect future reproduction.

Frequency of Reproduction; Life History Patterns

Reptilian species range from those that produce many clutches per year to those that reproduce only once every few years (Vitt and Caldwell, 2014; Mesquita *et al.*, 2016). For example, oviparous snakes commonly have one clutch annually; relatively few are reported to reproduce more than once per year. In contrast, oviparous lizards that live in warm and temperate environments often produce 5 or 6 clutches of eggs per year. As an extreme case, female leatherback sea turtles (*Dermochelys coriacea*) can yield 10 clutches with up to 90 eggs each in a reproductive season. Climate and reproductive seasonality can play a key role in affecting clutch frequency. Some turtles produce 4 clutches in the southern part of their range, but only 1 clutch annually at their northern geographical limit. In marked contrast to oviparous species that yield multiple clutches annually are those that do not reproduce each year. For example, female marine iguanas (*Amblyrhynchus cristatus*) of the Galapagos Islands reproduce on a biennial cycle. Likewise, some sea turtles breed once every 3 years. Tuataras reproduce no more frequently than once every two years, and on average, only once every 4–5 years (Cree, 2015).

Unlike typical oviparous lizards, viviparous squamates usually are restricted to a single litter annually (Blackburn and Stewart, 2011; Stewart and Blackburn, 2015). This restriction is readily explainable in seasonal environments, given the duration of pregnancy relative to the time available for reproduction. Nevertheless, a few live-bearing species (including certain chameleons and garter snakes) have been reported to accomplish more than one pregnancy in a single year. More common among viviparous species are reports of biennial and triennial reproduction. A number of live-bearing lizards and snakes from multiple families reproduce on a 2 or 3 year cycle. For example, various New Zealand geckoes reproduce biennially. In northern populations of the timber rattlesnake (*Crotalus horridus*), females reproduce only once every 3–4 years. The infrequency of reproduction reflects their extreme climatic conditions, coupled with the high costs of reproduction in such an environment. Snakes that skip reproductive years can replenish lipid stores before beginning another cycle.

Frequency of reproduction is best viewed in the context of overall life history patterns that also take into account clutch size, adult body size, and time to reach maturity (Mesquita *et al.*, 2016). Lizards have received considerable attention in these respects (Vitt and Caldwell, 2014). A classic analysis of oviparous lizards recognized three life history patterns: (a) production of one clutch annually, with delayed maturity (>1 year after hatching) coupled with large body size (as in the green iguana); (b) production of multiple clutches per year, in small bodied forms with early maturity (at less than 1 year of age) (as in anole lizards); and (c) production of multiple clutches by large bodied lizards with delayed maturity (as in basilisk lizards). Regarding the third pattern, large body size allows for larger clutches; meanwhile, delayed maturity can reflect resource limitations as well as the time needed to achieve large body size. Another analysis of lizards further divided the categories above, since some single-brood lizards yield small clutches, and some large-bodied forms exhibit early maturity. The lizard categories do not apply well to oviparous snakes, which commonly have no more than a single clutch annually.

Reproductive Cycles

Reptiles vary with respect to when mating occurs relative to gonadal growth and sex steroid secretion (Pough *et al.*, 2016). In the "associated gonadal cycle," gametogenesis and maximum hormone release occur shortly before mating, which is soon followed by fertilization. In the "disassociated gonadal cycle," mating and gonadal activity occur at different times of year. This pattern is made possible by sperm storage by the male or the female. The advantage of dissociated cycles is that gametogenesis and mating each can be scheduled when their energetic costs are minimal. Associated gonadal cycles are typical of crocodilians and most lizards, and occur in tropical/subtropical environments with long periods apt for reproduction. Disassociated cycles occur in both temperate and tropical climates, and often occur in turtles and snakes.

Reproductive cycles also can be characterized by duration and time of year (Mathies, 2011; Vitt and Caldwell, 2014; Méndez de la Cruz *et al.*, 2015; Pough *et al.*, 2016). In aseasonal cycles, reproductive activity occurs all year round, a common feature of reptiles in tropical and subtropical environments. Three forms of seasonal cycles have been distinguished. One is the "discontinuous" cycle, in which adult activity is restricted by seasonal changes, requiring that fertilization and embryonic development be accomplished during a few months of a single reproductive season. In this pattern, as in many temperate zone reptiles of North America, mating and fertilization occur in the spring and hatchlings or neonates emerge in the late summer. Discontinuous cycles also occur in tropical environments with seasonal patterns of rainfall. In such environments, reproduction can be timed to minimize reproductive costs to females or alternatively, to maximize survival of the offspring.

In a second type of seasonal cycle, the timing of egg production and hatching are uncoupled because embryos remain in the eggs through developmental arrest. For example, in some tropical turtles, fully-developed offspring remain in the eggshell during dry periods, and only hatch when conditions improve. A striking example is represented by the Madagascan chameleon *Furcifer labordi*. Eggs incubate for 8–9 months after oviposition, hatching synchronously at the beginning of the rainy season. The hatchlings reach sexual maturity in <2 months, reproduce, and die; thus, most of the life of individual chameleons is spent as an egg.

A third type of cycle is the “continuous” seasonal variety, in which reproduction takes most of the year to complete. This pattern is common in lizards of cool montane habitat and far southern distributions. Thus, in the North American lizard *Sceloporus jarrovi*, females mate in the fall, overwinter while pregnant, and give birth in the spring. This pattern maximizes the time neonates have to feed before the following cold period. Likewise, in one population of the New Zealand gecko *Hoplodactylus maculatus*, the female mates in the summer, stores sperm during the winter while oocytes are accumulating yolk, becomes pregnant in the spring, and gives birth a full 14 months later. Another example of a continuous seasonal pattern is the tuatara, in which eggs reside in the oviducts for 6–8 months, are oviposited, and then incubate for about a year before hatching (Cree, 2014).

Lipid Cycles

Reproductive activity in reptiles is partly fueled through lipid stored in the form of abdominal fat bodies. Consequently, lipid cycles (as measured through changes in total mass of the fat bodies) commonly reflect cyclic reproductive patterns, including vitellogenesis, spermatogenesis, and behaviors related to reproduction. In general, lipids are stored when resources are most available, and used during periods of energetic needs are maximal.

Lipid cycles can differ between males and females of a species when patterns of maximal energy use differ between the sexes. An example is provided by the viviparous skink *Mabuya heathi* of Brazil, a species that breeds cyclically in accord with wet – dry seasonality (Vitt and Caldwell, 2014; Stewart and Blackburn, 2015). This species is highly unusual in that females provide most of the nutrients for development by placental means, during the last few months of an 8–12 month gestation. In males of this species, mass of the fat bodies and the testes grow to a peak during the dry season (when resources are less abundant); both decline during the wet season, when mating occurs. In females, fat bodies decline during the dry season, during the time that maternal transfer of nutrients to the embryos is maximal. The timing of gestation ensures that offspring are born at the beginning of the wet season when nutrients are most abundant. Lipid cycles in females thus reflect embryonic and neonatal needs, and lipid cycles in males are timed to accommodate female readiness for mating.

Environmental and Hormonal Control

In reptiles that reproduce seasonally, environmental cues indicate optimal times of reproduction (Krohmer and Lutterschmidt, 2011; van Dyke, 2015). Species vary as to whether seasonal reproduction is under control of an endogenous cycle, or is influenced by exogenous cues, or both. Temperature is the most important environmental cue in many species, although photoperiod can play a secondary role. In some tropical species, seasonal rainfall stimulates reproductive activity. Detection of day length is mediated through the parietal-pineal complex, which in turn acts via melatonin secretion.

Neuroendocrine control of reproductive cycles in males and females has been studied intensively in some reptiles (Krohmer and Lutterschmidt, 2011). The hypothalamic-pituitary axis communicates environmental and social cues to the gonads. The gonads in turn stimulate accessory reproductive structures (including the oviduct and abdominal fat bodies) as well as behaviors, via the sex steroids. Given that gametogenesis and hormone production can either be associated or disassociated, with patterns that can differ between the sexes, environmental cues must act in a diversity of ways.

Specialized Aspects

Sperm Storage

In many reptilian species, females have the ability to store sperm in their reproductive tracts (Blackburn, 1998; Cree, 2015; Siegel *et al.*, 2015). This ability uncouples the timing of mating vs. ovulation/fertilization, such that each activity can be optimally timed for the benefit of the female and/or her offspring. In alligators, sperm are stored only within a given reproductive season; however, in turtles and squamates, sperm can be stored for several years. Male reptiles also can store mature sperm in their reproductive tracts (vas deferens or epididymis), a pattern that allows spermatogenesis and mating to be at different times of year. Many squamates store sperm crypts or tubules in the non-glandular uterus of the oviduct. In snakes and several lizard groups, storage structures for sperm are located in the posterior infundibulum of the oviduct. In snakes, these structures are sac-like receptacles associated with ciliated ducts. In garter snakes, cells of these receptacles provide nutrition for the sperm in the form of lipids and carbohydrates. In alligators and turtles, sperm storage tubules can be located in the posterior infundibulum as well as in the posterior uterus. The diversity of female structures for storage of sperm reflects multiple evolutionary origins.

Parental Care

Although most reptiles abandon their eggs following oviposition, various degrees of parental care have been documented in more than 100 species (Shine, 1988; Stahlschmidt and DeNardo, 2011). Parental care is extensive in crocodilians, in which one of the

parents (usually the female) guards the nest. Crocodiles and alligators not only construct the nest, but facilitate hatching, carry the young by mouth to the water, and remain with them to guard against predators. Although parental care is rare in chelonians, nest-attendance has been documented in an Asian tortoise species.

Despite the fact that parental care of eggs or offspring has been reported in less than 1% of the squamate species, it is broadly distributed and manifested in multiple ways (Shine, 1988; While *et al.*, 2015). Among lizards, egg-attendance (sometimes called “brooding”) is the most common form of parental care. It has been observed in species scattered among 12 families, including alligator lizards, skinks, varanids, and iguanids. Female skinks of the genus *Plestiodon* not only guard their eggs against predators, but remove eggs that become infected, and regulate hydric and thermal conditions of the eggs by coiling around them and by changing their positions in the nest. In two species of this genus, the mother facilitates hatching. Similarly, in some viviparous skinks, females help the newborns emerge from their fetal membranes at birth.

In snakes, maternal attendance of the eggs or young commonly is found in large or venomous species such as crotalids and elapids, but also occurs in some species of other families (Stahlschmidt and DeNardo, 2011). For example, in some *Psammophylax* of the family Colubridae, female snakes coil around their developing eggs for up to 6 weeks. Pythons of at least 3 genera bask in the sun, and return to the nest to transfer heat to the eggs. In at least a few python species, females warm their eggs by generating heat via muscle contraction.

Some squamates exhibit maternal care of the young after birth or hatching (While *et al.*, 2015). Such care ranges from tolerance of the offspring to their active defense. Various geckoes and skinks aggressively protect their young from conspecific predators. In certain viviparous pit vipers, the female remains with the young for several weeks after birth. In *Egernia* skinks (in which males and females can maintain long-term pair-bonds), juveniles can remain in the parental home range for years.

Parental care is hard to observe in nature, and probably is more broadly distributed among reptiles than we now recognize. Such care has a long evolutionary history; fossil evidence indicates that several species of extinct dinosaurs had parental care of the eggs and young. Thus, the well-known patterns of parental care in birds may have had their origins in their dinosaurian ancestors.

Viviparity

Although most reptiles lay eggs, viviparity (live-bearing reproduction) occurs in nearly 20% of squamates, including representatives of 27 families (Blackburn and Stewart, 2011; Stewart and Blackburn, 2015). Among its advantages, viviparity allows the pregnant female to incubate her embryos at optimal temperatures for development. In addition, viviparity helps protect eggs from predation and from environmental threats (such as temperature extremes and dehydration). Viviparity also allows species to inhabit environments unsuitable for egg-laying, such as aquatic and arboreal habitats. Much evidence supports the idea that viviparity allows pregnant females to manipulate conditions of gestation to promote neonatal quality and/or maternal survival. In addition, during gestation, the female provides oxygen, water, and calcium to the embryos via placental organs formed from apposition of fetal membranes to the oviduct lining. In some species, most of the nutrients for development are provided by the placentas, which are correspondingly specialized morphologically. Viviparity has been shown to have evolved among squamates in at least 115 separate clades. This pattern is a focus of considerable research with regard to how it is accomplished and how and why it has evolved (Blackburn, 2006).

Parthenogenesis

Some reptiles reproduce asexually via parthenogenesis. In this pattern, females produce female offspring without the need for fertilization (Pough *et al.*, 2016). This pattern occurs in more than 50 lizard species from 8 families (including geckoes, lacertids, agamids, and teiids). It also has been documented in the blind snake, *Indotyphlops braminus*. Among the best-studied forms are teiid lizards of the genera of *Cnemidophorus* and *Aspidoscelis* of the American continents. As in other parthenogenic squamates, the unisexual teiids have resulted from hybridization of two bisexual species. Unisexual *Aspidoscelis* engage in courtship and “pseudo-copulation” in which one female mounts another, a pattern that may enhance gonadal activity. Because reproduction involves clonal inheritance, parthenogenic offspring lack the genetic variation of sexual species. In the absence of genetic diversity, evolution by natural selection is inhibited; thus, such populations have poor prospects for long-term survival. In several species of snakes as well as monitor lizards, individual females have exhibited facultative parthenogenesis under conditions of captivity. This pattern occasionally has been documented in nature among snakes, a situation of current interest due to its potential evolutionary significance (Booth and Schuett, 2016).

Bird Reproduction Overview

Elisabeth Blesbois, INRA (French National Institute of Agronomic Research), Paris, France

© 2018 Elsevier Inc. All rights reserved.

Introduction

Birds constitute a unique vertebrate animal class which physiology has evolved in order to permit flight and adaptation to highly different environments and climates. In addition to other specific physiological adaptations such as air bags and feathers, birds have developed an original reproductive process that allows an efficient transmission of the genome from one generation to the next in changing environments. The bird females produce telolecithal (large amount of vitellus at the vegetal pole) hard-shelled eggs, enabling the autonomous development of the embryo in a highly protected microenvironment. In most birds, only one oviduct is present in the adult female allowing a good management of the abdominal space that is expected to receive daily (in laying hens, common ducks and quails) a very big egg highly enriched in vitellus, and surrounded by white albumen and shell. The female is the heterogametic sex since the female chromosome pair is ZW while the male pair is ZZ. The presence of sperm storage tubules (SSTs) in the single avian oviduct dedicated to prolonged sperm storage provides “adaptive freedom” to the female in order to sustain fertilizing potential even in the absence of males. Most birds face annual reproductive cycles that vary with the climates. In mild climates the winter/spring growing photoperiods are the main factors acting to induce bird reproduction cycles while in desert climates, temperatures and water availability are important for the reproductive success. All the reproductive features observed in birds have a unique objective, ensure the highest viability of the progeny. In the migratory species, the young birds of the year need to be strong enough at the time of the migrations in order to support long flights and food privations. For that reason also, when eggs are destroyed, or removed for the nest, the bird female is able to lay an added egg. Humans have used this property to increase the egg production in domestic birds. Joined to an efficient system of artificial incubation of the embryo, the egg and chick production have consequently been considerably increased during the last centuries in species such as the chicken.

Based on this strategy (removing the eggs to stimulate added egg production, embryonic development through a “host” system), a mean of 15 bird species have been domesticated since more than 7000 years allowing a diversification in human diet. Egg and meat poultry production constitute nowadays one of the main animal protein source for human diet.

In this article, we will present the main specific features of the bird reproductive processes that contribute to the species evolution and are of huge importance for the management of genetic resources and biodiversity.

A Specific Female Reproductive Tract

The female bird reproductive system presents common features with reptiles by their oviparity and the long storage of sperm in specific places of the female tract. It shows also common features with mammalian reproduction by the chromosome determination of the sex and by the constant temperature needed for the oogenesis. But female bird reproduction presents specific features: the development in most bird species of a unique ovary and oviduct (with the exception of the some raptors or the kiwi), the structure in ovarian cluster of the ovary that makes precise the vitellus incorporation in the oocyte, the follicular hierarchy, the oocyte structure, the very high specialization of different parts of the oviduct.

An Ovarian Bunch With a Unique Follicular Hierarchy for the Production of Oocytes Enriched in Vitellus

The development of the ovary starts early in the embryonic life in the hen. Undifferentiated gonads are already visible at 3.5 days of incubation. The primordial germ cells (PGCs) that are in multiplication since the lay, migrate from the epiblast to the embryonic gonad via the blood circulation at approximately 5.5 days of incubation. Then the female PGCs follow their multiplication and start their differentiation in active oögonies that multiply under endocrine control (FSH, the sexual steroids estradiol and progesterone). In most cases, the right and left genital tracts start their development during the early embryogenesis but the right ovary and oviduct rapidly regress (day 8 of incubation in the hen) under the control of the AMH produced by the left ovary (Jacob and Bakst, 2007).

The entry in meiosis of the oögonies starts at approximately 14 days of incubation in the hen. The left ovary contains a mean of 500,000 primary oocytes (Stage prophase diplonema) at the time of hatching but only a small number of these oocytes is recruited at the puberty in order to undergo the next stages of maturation. The oocytes are in the cortical part of the ovary at hatching, and somatic cells (future follicular envelopes) rapidly surround them. The undifferentiated follicles (cortical follicles) grow up to the 3 months (low growing) and then stop up to the puberty (12–18 weeks old). The follicles, recruited under the FSH control after the puberty, undergo a new growing stage and accumulate proteins and a few lipids to form the white follicle. It then migrates at the ovary surface and undergoes great growing (hierarchical folliculogenesis, 5 days length in the hen) during which the meiosis maturation and the deposition of lipoproteic compounds of the vitellus occur. The follicles sequentially grows from the F6 stage (small yellow follicle) up to the F1 stage (ovulatory follicle, Figs. 1 and 2). They do not share an antral cavity as in mammals. The oocyte is surrounded in the follicle by granulosa cells (one layer) and by two theca (internal and external, of mesenchym origin). The theca produce the estradiol in birds, the granulosa produces mainly the progesterone. The external theca production of estradiol is already maximal at the early great growing follicular stage and then decreases from the F4 stage to disappear at

Fig. 1 Hen ovary and follicles (Photos Elis S., INRA). (a) The ovary includes in its central part small follicles named white follicles that have not yet started to accumulate vitellus. At the periphery of the ovary the yellow follicles are under rapid growing and accumulation of vitellus. The biggest follicle is the F1 follicle ready to be ovulated. (b) From the left to the right, the different stages of the follicular hierarchy, from F6 to F1. Reproduced from Blesbois, E., 2011. Gamètes et fécondation chez les oiseaux. Inra Productions Animales 24(3), 259–272.

Fig. 2 Follicle and oocyte (Diagrams and photo Elis, S. INRA). (a) Diagram of F6 follicle just before the ovulation. The germinal disc contains the female pronucleus and is located in an area of the oocyte names “animal pole”. The opposite area that contains only vitellus and RNAs is called “vegetal pole”. (b) Diagram oocyte at the time of ovulation. The somatic cells of the follicle have been removed at ovulation. (c) Photo of the animal pole of the desmature oocyte. The central more dense area is the germinal disc. Reproduced from Blesbois, E., 2011. Gamètes et fécondation chez les oiseaux. Inra Productions Animales 24(3), 259–272.

the F1 stage while the granulosa production of progesterone increases, inducing at the end the ovulation under LH control. The mature oocyte is then captured by the infundibulum part of the oviduct (equivalent to the mammalian ampulla) by peristaltic movements. The mature ovulated oocyte is very different from the mammalian one. Its main diameter varies a lot with the species (8–10 cm in the ostrich, 3–5 cm in the hen, only 1 cm in some Passeriformes). The mature oocyte is mainly composed of vitellus (or yolk including lipoproteic fractions, proteins, steroids, thyroid hormones, growth factors, etc.) needed to ensure the diet and growing of the future embryo. A layer of “extra-embryonic” RNA with unknown role is present at the periphery of the vitellus. At the animal pole of the vitellus, the germinal disc contains most of the cellular organelles, a stock of “embryonic” RNA, different proteins, vitellus and the haploid female pronucleus containing, among others, the Z sexual chromosome (to make a male chick) or the small W (to make a female chick). A plasmatic membrane and an extracellular inner perivitelline layer (IPVL) surrounds the ovulatory oocyte. The IPVL is mainly composed of ZP proteins and is the initial point of contact between sperm and oocyte at fertilization. This IPVL is more or less the homologous of the fish chorion or the mammalian zona pellucida. However, contrary to the zona pellucida, the bird IPVL authorizes the transfer of 10–15 spermatozoa inside the oocyte and is not an interspecies barrier. This last property permits interspecies hybrids (i.e., mule ducks, pheasant-hen, quail-hen hybrids). Some IPVL ZP show original synthesis places since the liver synthesizes the ZP1, the granulosa synthesizes the ZP3 and the oocyte the ZPD (Elis *et al.*, 2008).

In case of fertilization, the oocytes RNA ensure alone the high number of zygote cells multiplication during the first 24 h of the embryo development in the oviduct.

A Multi-Functional Oviduct

The left oviduct develops in the young embryo from the left Muller canal while the right one regresses. At sexual maturity (20–25 weeks old in the hen), the oviduct is a long tube composed of five specialized areas (Fig. 3; Sauveur, 1988), suspended by two ligaments at the abdominal ring. The upper part of the oviduct is the infundibulum where the ovulated oocyte is captured. The infundibulum is the site of fertilization. It contains semen storage places (tubules or folds depending on the species) where the sperm that come from the SST of the utero-vaginal junction may wait for the oocyte. After the fertilization that occurs less

Fig. 3 The hen genital tract. (a) Diagram of the female tract (Reproduced from Sauveur, B., 1988. *Reproduction des volailles et production dœufs*. INRA Paris, ISBN 2-85340-961-9 p. 20, 231.). The central part of the figure represents all the segment of the tract, from the ovary in the upper part of the diagram to the opening of the vagina in the cloacum, in the lower part of the diagram. The fine lines are artificial representations of the delimitations of each part of the upper oviduct (infundibulum, magnum, isthmus). The time indicated near to the name of each compartment represents the mean time spent by the egg in each part of the oviduct. On the left part of the diagram, there are annex diagrams representing the stage of the embryo development in the corresponding part of the oviduct on its right. First divisions of the zygote in Morula in the isthmus (the four cells of the morula described here are in syncytium (opened cells)). Primary blastula in the upper uterus. Secondary blastula when the egg is oviposited (or layed). (b) Photo of a hen oviduct with an egg in the uterus (shell gland).

than 30 min after the ovulation, an external perivitelline layer (EPVL) is secreted in the infundibulum around the fertilized oocyte in order to increase the cohesion and strengthen of the egg. The EPVL contains many components with proteins such as lysozyme, ovomucin, ovomucoid, VMOI I. The fertilized oocyte, now more robust, spends then 3 h in the second part of the oviduct, the magnum that secretes the main proteins of the albumen or egg white (more than 12 different protein families, 50% of ovalbumin). During the stay in the magnum, at the germinal disc, the fusion of the male and female pronuclei occurs 3 h after the fertilization. The first divisions of the zygote takes place 1 h later in the isthmus giving a morula. The white egg hydration occurs also in the isthmus where the egg stays approximately 1.5 h and continue in the uterus (or shell gland) where it stays a mean of 20–22 h in the hen. The isthmus is also the place of secretion of the shell membranes and a first part of the shell, the rest being deposited in the uterus. The divisions of the new zygote continue at a very high rate during the stay of the embryo in the uterus. They are firstly perpendicular to the surface of the germinal disc, then parallel. The morula moves to a blastula and a subgerminal cavity, the blastocoele appears. After passage through the uterus, the whole shell surrounds the egg that rapidly cross the vagina with the help of peristaltic contractions before the oviposition (lay). The oviposition is also the time of the first activation of the young embryo genome. At this stage, the embryo (secondary blastula) contains 30,000–50,000 cells in the hen. At the mother endocrine level, a LH pic precedes the oviposition and has an action to stimulate the next ovulation that occurs approximately at the same time in the upper oviduct of the laying hen.

The embryo is then ready to follow its development under conditions of broodiness or artificial incubation, but it may also stay some weeks without development, waiting for the good conditions for its new history.

A Quite Simple Male Reproductive Tract

The avian male reproductive system is much simpler than the female (Fig. 4; De Reviers, 1988). The two internal testis, close to the kidneys, produce sperm in one-two weeks depending on the species (12 days in the chicken). The spermatogenesis occurs at the internal body temperature (41°C in most birds) at the opposite of mammals. After their liberation from the testis, the sperm undergo an “expeditious maturation” in the epididymis and deferent ducts that do not contain annex glands. The sperm are expelled at mating from the deferent duct to the female vagina, via genital papillae through a cloacal eversion of the two partners. A small number of bird species have a phallus (i.e., muscovy duck).

Fig. 4 Diagram of the internal male genital tract of a male fowl in reproduction. De Reviers, M., 1988. *Le Mâle en Reproduction*. Reproduction Des Volailles et Production d'œufs. Paris: Ed INRA, pp. 141–206.

The early differentiation of the gonad in testis occurs at 5.5 days of incubation in the chicken. The male PGCs that share the Z sexual chromosome migrate into the young gonad at this stage, and sertoli cells are placed around the PGCs, and seminiferous rings are rapidly visible. The embryonic mesonephros contributes to the differentiation of interstitial cells in leydig cells. The Wolf canal differentiates into epididymis and deferent canal as in mammals. The two male tracts follow their growing after hatching. Sertoli cells proliferate up to 7 weeks of age in the chicken and then differentiate. In the adult, the spermatogenesis occurs in seminiferous tubules that account for 90% of each testis volume. By contrast to mammals, the sperm that leave the testis already possess most of their fertilizing capacity and a part of their motility. During their transit in the epididymis and deferent duct, they acquire their full motility capacity in a rapid trip (24 h in the chicken). The principle of the sperm production seems to be, make the highest number of sperm (1–5 billion sperm/ejaculate in the chicken) as fast as possible.

The Hard Life of Bird Sperm

By opposite to the “expeditious” gamete production in the male, a difficult travel wait for the sperm that arrive in the female vagina. The competition is very hard and will be present even after the entry of many sperm inside the oocyte for the polyspermic fertilization.

The Sperm

Bird sperm are thin and long cells composed of a head (acrosome and nucleus), a midpiece and a flagellum (Fig. 5; reviewed by Blesbois, 2012). The acrosome is small and contains the acrosome vesicle that constitutes a calcium reservoir and contains the

Fig. 5 The fowl sperm. (a) Diagram of the main parts of the sperm, from the acrosome in the upper part of the diagram to the start of the flagellum in the lower part of the diagram (Reproduced from De Reviers, M., 1988. *Reproduction des volailles et production d'œufs*. INRA Paris, ISBN 2-85340-961-9, p. 20, 151.). (b) A photo a fowl sperm colored with eosin-nigrosin (the viable sperm appears more or less white and the environment red) observed under phase contrast microscopy (photo I. Grasseau, INRA). Reproduced from Blesbois, E., 2011. *Gamètes et fécondation chez les oiseaux*. Inra Productions Animales 24(3), 259–272.

proteolytic enzymes needed to hydrolyze the IPVL and penetrate inside the oocyte at fertilization. A perforatorium (mainly actine) is present under the acrosome vesicle but its role is still unknown in birds. The nucleus is highly condensed for an optimal protection of the genes during the sperm travel. A helicoidally ring surrounds the sperm head only in specific species (Passeriformes). The mid-piece is composed of a proximal and a distal centriole for the motility need, and of a mitochondrial sheath that contributes to the energetic metabolism. Sperm motility is required for key actions such as reach the SSTs and initiate fertilization. Mitochondria are also present in a part of the flagellum of some species such as the quails. Finally, the number of sperm mitochondria varies a lot with the species: a mean of 30 in the chicken and the turkey, 1000 in the quail. The flagellum is the longest part of the sperm (70–90 μm in the chicken, 140 μm in some quails). It contains an axoneme that follows the distal centriole and contains one central doublet and nine distal doublets made of microtubules containing dynein dimers (close to mammalian sperm axoneme). In most birds (except Passeriformes), the axoneme is surrounded by a fibrous sheath in the longest part of the flagellum.

At the ejaculation time, sperm are surrounded by a seminal plasma that contains many compounds. Some of them are suspected to protect sperm to premature proteolytic attacks, other to sustain metabolism and other to be only by products of degradation (Blesbois, 2012; Labas *et al.*, 2015).

Conservation and Selection of Sperm in the Female Tract

When sperm arrive in the vagina, the seminal plasma is rapidly discarded and a hard selection starts. Only 1% of the sperm deposited in the vagina reach the SSTs, then 1% of them reach the fertilization site in the infundibulum. 99% of the male gametes are thus eliminated during their transit in the female tract that acts as a succession of filters. The selection to reach the SSTs depends on the motility capacity of each sperm and of different mechanisms including immune actions or vaginal peristalsis (reviewed by Blesbois and Brillard (2007), Stepinska and Bakst (2007), and Blesbois (2012)). The SSTs constitute one layer tubules glands (Fig. 6). Their number differ a lot with the species 150–20,000 depending, among others, on the length of storage of sperm in the SSTs (5 days in some Passeriformes, 3 months in Turkeys). In the hen, the length of fertile period after a single insemination or mating is close to 3 weeks with an optimal fertility (often near to 100%) in week one and then a gradual decrease. The sperm are released from the SSTs by mechanisms that are still discussed (i.e., quite passive; involving specific metabolic capacities, etc.) and cross the upper parts of the oviduct where they meet the previously fertilized egg that goes in the opposite way. In the uterus, the sperm face to an environment highly enriched in calcium (up to 15 mM) for the shell egg calcification, a factor that could be suspected to induce acrosome reaction (AR) of not well-protected sperm. Bird sperm do not undergo the so-called “capacitation” observed in mammals to prepare the gamete to fertilization by removing different protection systems. In birds, the acrosome reaction (RA) that allows sperm to release their enzymes contained in the acrosome vesicle and is the inaugural event of fertilization, occurs at the contact of the IPVL of the newly ovulated oocyte in the infundibulum. The RA needs extracellular calcium, is highly energy consuming and involves the activation of many signaling pathways (Lemoine *et al.*, 2009). Many sperm undergo the RA, and many of them

finally penetrate into the oocyte and differentiate in male pronuclei. The physiological polyspermy is denser at the animal pole of the oocyte. However only one male pronucleus merges with the female pronucleus in order to make a zygote. This access to the syngamy constitutes the last filter of selection of the male gamete.

Reproduction Cycles Adapted to Environmental Changes and/or Poultry Production Needs

Most of the wild species of birds show annual cycles of reproduction, the growing of the young birds occurring at the best moment of the year. In mild climates, spring is the best season for hatching, the reproduction is initiated by growing photoperiod and is maximum in long photoperiods. In tropical and equatorial areas where the variations of the day length are small, other outside stimuli such as available diets or water or suitable temperatures are more important. As an example, the sexual maturity of Australian Emus starts in (low) decreasing day length.

A “reproductive molt”, also called “premarital molt” (renewal of the feathers, often partial) indicates the entry in the annual reproduction period. Gonads grow at the same time. After this molt, the males often show a bright plumage that will support courtship rituals, and the females will prefer the most beautiful and robust males for mating! At the end of the reproductive period, another molt signs the removal of the reproductive plumage, the regression of the gonads and the stop of gamete production. Molt may be artificially induced in domestic birds in order to accelerate the renewal of the cycle.

In the domestic birds, the annual cycles are often less clear or even suppressed. The eggs freshly laid by the females are usually removed at each lay in order to stimulate new lays, if the photoperiod, diet and temperature conditions stay good. The fertilized eggs are incubated in order to produce chicks while the females continue to lay. This system has been the basement of the industrial production of poultry. Nowadays, the laying hens show a daily cycle of lay. At the same time, a hen lays one egg and an oocyte is ovulated in the infundibulum to be fertilized and laid the following day. In the poultry practice, the intervals between matings or artificial inseminations must take into account this daily cycle since the vaginal peristalsis that surrounds the lay, decreases the capacities of sperm to cross the vagina in order to reach the SSTs.

In the poultry breeding practice, an efficient genetic selection added to controlled photoperiods and diets adapted to the very high energetic level needed for an intense egg production, allowed the optimization of the lay. Laying hens, quails and common ducks may lay throughout the year with short “daily” cycles (up to more than 300 eggs produced per year in specific lines). It is not the case for the “meat” breeds. These breeds, selected mainly on their growing potential, often show poor reproduction capacities. They encounter problems of breeding, gamete production, mating, behaviors that depend on the species but must be taken into account in the selection programs of the 21st century.

Different reproductive biotechnologies have also emerged in birds: artificial incubation, artificial insemination, semen storage (reviewed by Blesbois, 2011), Primordial Germ cells methodology (reviewed by Whyte *et al.*, 2016) rely on the specific features of bird reproduction, and contribute to the growing of the poultry productions and also to conservation programs through the world.

Conclusion

Bird reproduction involves oviparity and a very complex system of internal fertilization. If the male shows highly visible external sexual attributes, its internal reproductive system turns toward an expeditious production of a maximum of gametes in a short time. By opposite, the female genital tract is very sophisticated, reaching a very high level of precision of the different steps leading to the egg production that has been the support of the development of the poultry productions. Modern laying hens export in their eggs more than 10 times their weight per year for the daily egg production, and the poultry productions constitute nowadays one of the first protein source for the human diet need.

Glossary

Albumen Egg white, a mixture of proteins secreted by the oviduct.

Broiler A chicken selected for rapid growth and meat production.

Broiler breeder parent Parents of chicken selected for rapid growth and meat production.

Commercial egg layer Chickens bred for egg production.

Egg A hard shelled structure encasing albumen and yolk-filled oocyte.

Oviduct Female reproductive tract that produces albumen, shell membrane, and shell and lays around yolk-filled oocyte.

Oviposition Expulsion of egg from the female reproductive tract.

Ovulation Release of yolk-filled oocyte by rupturing the largest follicle.

Prehierarchical follicle Ovarian follicles that are 6–12 mm in size.

Preovulatory follicle Large ovarian follicles that are greater than 12 mm in size.

Small white follicle Small follicles that are less than 5 mm in size and appear white in color.

Sperm storage tubule Folds of mucus membrane at the uterovaginal junction that stores sperm.

Yolk Lipoproteins stored in the oocyte cytoplasm.

Bullet Points

- Commercial egg-type chickens are genetically selected to lay 280–300 eggs in 52 weeks.
- Appropriate stimulation of hypothalamic photoreceptors and activity of several groups of hypothalamic neurons are critical to the onset and sustenance of ovarian follicular development and maturation.
- Ovarian follicular selection, maturation and ovulation is a highly coordinated process regulated by pituitary gonadotropins and intra-ovarian growth factors.
- Different regions of oviduct secrete albumen, shell membrane, and shell components.
- Broiler breeder parent hens fed *ad libitum* develop excessive ovarian follicles and have poor egg production.
- Egg-type chickens develop epithelial ovarian carcinoma likely due to high rate of ovulation within 3 years of age.

Introduction

The modern day chicken (*Gallus gallus*) reared for table egg production and meat production are descendants of Red jungle fowl and have undergone intensive genetic selection for several economically important traits such as egg/meat production, feed conversion efficiency and livability. As a result, the meat-type or broiler chickens grow rapidly and reach market weight in approximately 42 days after hatch. During this period, broiler chickens voraciously eat 4.1 kg of feed to achieve a 40-fold increase in body weight. Egg-type chicken is a prolific egg layer and lay 280–300 eggs over a period of 52 weeks. Such a high level of egg production is initiated and sustained by coordination among several organ systems, most notably hypothalamus, anterior pituitary gland, ovary, liver, and medullary bones. This article will use egg-type hens and broiler breeder parent hens to describe the control of reproductive system. As in mammals, the reproductive system in chickens is driven by hormones secreted by hypothalamus, pituitary gland, and ovary in response to a variety of external and internal stimuli.

Hypothalamus

Reproduction in chickens is primarily driven by neuropeptides secreted from hypothalamus (reviewed in [Joseph et al. \(2013\)](#)). Gonadotropin releasing hormone-I (GnRH-I), a hypothalamic decapeptide, is the primary neuropeptide responsible for controlling reproduction. Immunoreactive GnRH neuronal cell bodies are found in several areas of the brain most notably in olfactory bulb, hypothalamic septal and preoptic areas. GnRH-I immunoreactive axonal fibers are distributed in hypothalamic septal, preoptic, and tuberal regions. Dense immunostaining of GnRH-I axons are noticeable in organum vasculosum lamina terminalis and in the external zone of the median eminence. The latter provides an access to the hypothalamo-hypophyseal portal blood vessel to transport GnRH-I to the anterior pituitary gland. Chickens also express another isoform of GnRH, GnRH-II, whose cell bodies are located in the mid-brain and the GnRH-II axons were not found in the median eminence or in other areas of the hypothalamus. Immunoneutralization of GnRH-I but not GnRH-II results in decreased plasma LH levels and regression of the reproductive system suggesting that only GnRH-I is involved in controlling LH secretion from the pituitary gland. GnRH-II is likely to be involved in reproductive behaviors.

Regulation of GnRH-I Neurons

Photoreception

The domestic chicken is a long-day breeder; photoperiod duration greater than 14 h per day stimulates the hypothalamic-pituitary-gonadal axis. Numerous studies have attempted to identify the sites of photoreception and found that photoreceptors in eyes, pineal gland, and neurons in the hypothalamic suprachiasmatic nucleus as found in mammalian system are not important for perceiving photoperiodic signals in avian species. On the contrary, deep brain photoreceptors located in four hypothalamic nuclei (lateral septal organ, paraventricular nucleus, premammillary nucleus, and paraventricular organ) are capable of light perception (Kuenzel *et al.*, 2015). Neurons in these hypothalamic nuclei were found to express classical photopigments such as melanopsin/opsin 4, neuropsin/opsin 5, and vertebrate ancient opsin. Communication between deep encephalic photoreceptor sites and GnRH-I neurons remains to be elucidated. Certain wavelengths of light within the visible light spectrum are more stimulative to the photoreceptors than others. Both sighted and blind chickens exposed to red light or a combination of red, green, and blue lights laid more eggs than chickens raised with green light alone suggesting that red light was necessary to maintain ovarian activity and egg production (Baxter *et al.*, 2014).

Neuropeptides and Neurotransmitters

Both norepinephrine acting via α_1 adrenergic receptors and neuropeptide Y stimulates GnRH-I release from the neurosecretory terminals. Inhibitory control of GnRH-I secretion is exerted by dopamine and β -endorphin. Gonadotropin inhibitory hormone (GnIH), an RF-amide peptide, is likely to affect GnRH secretion and to inhibit gonadotropin secretion from the pituitary gland. RF-amides share a common carboxyl-terminal motif comprised of RF-NH₂ (R=arginine, F=phenylalanine). GnIH-immunoreactive neuronal cell bodies are found exclusively in the hypothalamic paraventricular nucleus, whereas the GnIH-axons are distributed throughout the brain including the external zone of median eminence, a region that has access to vasculature for transporting of GnIH to anterior pituitary gland. Immunohistochemical studies suggest that GnIH-axonal terminals lie in close apposition to GnRH-axons. GnIH may potentially be modulating the effects of photostimulation in avians. Melatonin receptor, Mel1c, is expressed in GnIH neurons and administration of melatonin restores GnIH mRNA levels following pinealectomy in quails. Melatonin was also found to increase release of GnIH peptide from hypothalamic explants. Recent studies suggest that green light inhibits GnRH-I expression by activating GnIH and GnIH receptor (GnIHR) expression in chicken hypothalamus. Green light exposure was found to increase GnIH content and GnIH-immunoreactive area in magnocellular region of hypothalamic paraventricular nucleus. Furthermore, green light also increases plasma melatonin levels with a concomitant decrease in expression of GnRH-I in neurons within nucleus of the pallial commissure (Zhang *et al.*, 2017). GnRH-I neurons also co-localized with GnIH receptor (GnIHR) while GnIH-neurons coexpressed melatonin receptor subtype quinone reductase 2. Another hypothalamic neuropeptide, kisspeptin that plays an important role in the onset of puberty and linking metabolic status with reproduction, has not been found in chickens. Both *Kiss1* and *Kiss2* genes and its receptor GPR54 have been presumed to be lost from the avian genome. Other neuropeptides that are known to affect reproduction in mammals such as dynorphin have not been explored in chickens.

Anterior Pituitary Gland

Reproduction is controlled by follicle stimulating hormone (FSH) and luteinizing hormone (LH), secreted by the anterior pituitary gland. Both FSH and LH are glycoproteins and composed of two-subunits: an α subunit that is common to FSH, LH, and thyroid stimulating hormone (TSH) and a β subunit which is unique to FSH, LH, or TSH. Gonadotropes or gonadotropin-secreting cells are found in both cephalic and caudal lobes of the pituitary gland. FSH and LH are secreted by two distinct populations of gonadotropes. FSH-producing cells are found in the periphery of the pituitary gland. LH-producing cells are more numerous than FSH-producing cells. FSH influences maturation of prehierarchical follicles and steroidogenesis in smaller follicles while LH promotes progesterone secretion from ovarian preovulatory follicles and induce ovulation.

Pituitary GnRH Receptor

Two GnRH receptors (GnRHR) have been identified in chickens: (1) GnRHR-I localized in the brain, pituitary, and gonads; (2) GnRH-2, also termed as GnRHR-III, expressed only in the pituitary gland. Both GnRHR are G-protein coupled receptors (GPCR) and when stimulated activates signal transduction pathways involving both inositol triphosphate and cyclic adenosine monophosphate (cAMP) suggesting the existence of both G_q and G_s subtypes of GPCRs. GnRH-I stimulates LH secretion by activating a pituitary-specific GnRHR (GnRHR-III). GnRH-III-immunoreactive cells are distributed throughout the adenohypophysis.

Pituitary GnIH Receptors

GnIH signals through a transmembrane receptor (GnIHR) that belongs to the GPCR family. Activation of chicken GnIHR was found to abrogate forskolin-stimulated intracellular increase in cAMP abundance suggesting that GnIHR is coupled to G_{α_i} and potentially inhibits adenylyl cyclase activity. GnIHR activation does not seem to affect intracellular inositol triphosphate levels

(Bedecarrats *et al.*, 2009). GnIHR-expressing cells are found in the chicken pituitary gland cephalic and caudal lobes wherein they colocalize with LH β mRNA-, or FSH β mRNA-containing cells. GnIHR mRNA quantity was significantly higher in the pituitaries of sexually immature chickens relative to sexually mature chickens (Maddineni *et al.*, 2008). Pharmacological doses of estradiol or a combination of estradiol and progesterone decreases GnIHR mRNA quantity suggesting that GnIHR gene expression is possibly down regulated in response to a surge in circulating estradiol and progesterone levels as the chicken undergoes sexual maturation to allow gonadotrophin secretion. Treating chicken anterior pituitary gland explants with GnIH peptide was found to decrease LH secretion. Although the presence of GnIH peptide in hypothalamo-hypophyseal portal blood is unknown, evidences suggest that GnIH may act as a counteracting system to GnRH stimulation within the pituitary gland (Baxter *et al.*, 2014).

Role of Gonadal Hormones on LH Secretion

Estradiol plays an inhibitory role in the control of LH secretion. Estradiol stimulates expression of progesterone receptor (PRR) in the pituitary gland. Progesterone acting via PRR either stimulates or inhibits LH secretion depending on the daily reproductive cycle of the hen. Inhibin, a hormone secreted by the granulosa cells of the preovulatory follicles, inhibits FSH β -subunit expression.

Ovary

The female reproductive system consists of a single ovary and oviduct in the chicken. By around day 10 of incubation, the right ovary and oviduct undergoes atresia under the influence of anti-müllerian hormone. The ovarian stroma and follicles are richly supplied with blood through ovarian artery that arises from the left renolumbar artery or the dorsal aorta. Abdominal and pelvic plexi of the sympathetic nervous system as well the posterior continuation of the sympathetic trunk innervate the ovary. The ovarian stroma is embedded with thousands of primordial follicles measuring less than 80 μ m in diameter that mainly consists of oocyte surrounded by perivitelline membrane (PV) and granulosa cell precursors (Fig. 1 Johnson, 2015). Primordial follicles remain in dormant state for months to years until activated for further development. Primary follicles measuring 80 μ m to 2 mm develop from this pool of primordial follicle by formation of basal lamina separating the granulosa cell layer from theca cell layer. The primary follicles are connected the ovarian stroma by means of a stalk that carries blood vessels and nerves. From the pool of primary follicles, several small white follicles measuring 2–6 mm emerge following deposition of protein-rich yolk but some of them further mature to

Fig. 1 Organization and structure of different types of ovarian follicles in a sexually mature hen. See Text for details. BL, basal lamina; GC, granulosa cell; GD, germinal disc; GV, germinal vesicle; PV, perivitelline membrane. Modified from Johnson, A.L., 2015. Reproduction in the female. In: Scanes, C.G. (Ed.), *Sturkie's Avian Physiology*, VI ed. Elsevier.

become prehierarchical follicles. Typically 8–12 prehierarchical follicles measuring 6–8 mm are present on the ovary and appear intense yellow due to the presence of carotenoids in the yolk. One of the prehierarchical follicles is selected almost every day in commercial egg-type chickens to undergo a rapid growth phase and join the preovulatory hierarchy. A typical preovulatory follicular hierarchy consists of 4–5 follicles termed as F1–F5 ranging in size from 12 to 36 mm in diameter (Fig. 2). F1 is the largest preovulatory follicle that will be ovulated next. A typical follicle consists of an oocyte whose cytoplasm is filled with vesicles of varying sizes each containing yolk lipoproteins (Fig. 3). The plasma membrane of the oocyte is surrounded by perivitelline membrane, a structure that is analogous to mammalian zona pellucida. Perivitelline membrane is composed of extracellular matrix and glycoproteins including zona pellucida proteins. A single layer of granulosa cells is found all around the perivitelline membrane. A basal lamina separates the granulosa cell layer and the theca layer. The theca layer is further divided into an internal and an external layer. While the theca cell layer is highly vascularized, the granulosa cell layer is avascular. Therefore, nutrients, hormones, and growth factors are transported by diffusion across basal lamina to reach granulosa cells and oocyte. Blood vessels are present throughout the surface epithelium of the preovulatory follicles except at stigma, the site at which the preovulatory follicle breaks open during ovulation to release the oocyte. The largest preovulatory follicle (F1) will undergo ovulation to release the oocyte. The post-ovulatory follicular membrane undergoes atresia over a 4–5 day period.

Follicular Selection and Maturation

Undifferentiated small white follicles (<1–3 mm) grow slowly under the influence of several autocrine or paracrine effects of growth factors and cytokines such as growth hormone, growth and differentiation factor-9 (GDF9), inhibins, activins, follistatin, and tumor necrosis factor- α (TNF- α). Rapid growth of multiple small white follicles is avoided by rendering both FSH receptor (FSHR) and vasoactive intestinal polypeptide receptor (VIPR) inactive by a mitogen-activated protein kinase activity. Removal of such inhibition and restoration of responsiveness to FSH and VIP leads to orderly follicle selection and entry of small white follicles into the pool of prehierarchical follicles (6–8 mm). A cascade of signal transduction events initiated by FSH signaling promotes transcription and translation of steroidogenic enzymes and steroid acute regulatory protein (STAR) leading to increased level of steroidogenesis. Members of the bone morphogenetic protein (BMP) plays a significant role in expression of FSHR and differentiation of granulosa cells in the 6–8 mm prehierarchical follicles. Granulosa cells are thought to be steroidogenically inactive

Fig. 2 Gross morphology of sexually mature chicken ovary. The ovary has 5 preovulatory follicles (F1–F5), one 9–12 mm follicle (SF) that is selected for further growth and future entry into the preovulatory hierarchy, several prehierarchical follicles (PHF, labeled on one), and post-ovulatory follicle (POF).

Fig. 3 Ultrastructure of a slow growing follicle. A part of the oocyte, perivitelline membrane (PV), a single layer of granulosa cells (GC), basal lamina (BL), and theca interna (TI) are shown. Note that oocyte has several yolk spherules (Y) and coated pits. Modified from Johnson, A.L., 2015. Reproduction in the female. In: Scanes, C.G. (Ed.), *Sturkie's Avian Physiology*, VI ed. Elsevier.

in follicles that are less than 10 mm in diameter while the cells located in the theca interna convert cholesterol to progestins and androgens. Androgens diffuse into the theca externa layer where they are converted to estrogens, a reaction catalyzed by aromatase. As the prehierarchical follicles enter the hierarchy of preovulatory follicles (>12 mm; also known as hierarchical follicles), they become more responsive to LH than FSH leading to heightened production of progesterone from granulosa cells. In addition, the granulosa cells produce inhibin A that inhibits FSH but not LH secretion from the anterior pituitary gland. Granulosa cells located in the germinal disc secrete BMP15 and GDF9 that control granulosa cell proliferation and progesterone production.

Role of Yolk Lipoproteins in Follicular Maturation

The precursors of yolk proteins (very low density lipoprotein and vitellogenins 1, 2, and 3) are synthesized in the liver under the influence of estradiol and gonadotropins and transported to the ovary through blood circulation. They diffuse out of the blood capillaries in the theca layer and pass through basal lamina and intercellular spaces between granulosa cells to reach the oocyte plasma membrane. Both very low density lipoprotein (VLDL) and vitellogenins (VTG) are transported into the oocyte by receptor-mediated endocytosis utilizing a 95 kDa VLDL receptor (VLDLR; reviewed in [Schneider \(2016\)](#)). Deposition of yolk lipoproteins is critical for further maturation and growth once a follicle enters the preovulatory hierarchy. Such requirement is evident from a mutant restricted ovulator (RO) line of the White Leghorn strain that carries a naturally occurring single nucleotide mutation in the VLDLR gene. Due to this mutation, RO hens fail to express a functional VLDLR protein on the oocyte membrane, which results in impaired uptake of circulating yolk precursor macromolecules. Consequently, VLDL and VTG accumulate in the blood, resulting in hypertriglyceridemia, hypercholesterolemia, and premature atherosclerosis. The RO hen ovary contains numerous large white follicles, small yellow follicles, and vitellogenic follicles, but most never reach full maturity, e.g., move from F4 to F1 in the follicular hierarchy.

Other Hormones Involved in Follicular Maturation

GnIH: A receptor for the hypothalamic GnIH was found to be expressed in both thecal and granulosa cell layers although existence of GnIH peptide in the circulation or in chicken ovaries has not been established. GnIHR mRNA quantity has been found to be lower in sexually mature hen ovaries compared with ovaries of sexually immature chickens. Treating sexually immature chickens with estradiol and/or progesterone decreases ovarian GnIHR mRNA abundance. Treatment of prehierarchical follicular granulosa cells with chicken GnIH peptide decreases basal but not FSH-stimulated cellular viability. Collectively, GnIHR may be involved in inhibition of ovarian follicular development. **Adipokines:** Leptin, an adipose tissue secreted hormone, affects energy balance and reproduction in mammals. Although mammalian leptin was discovered more than two decades ago, the authentic avian leptin

was discovered recently (Seroussi *et al.*, 2016). The avian leptin shares little homology to mammalian leptin and is expressed predominantly in the brain followed by ovaries. Considering the circulating levels of leptin are negligible, locally produced leptin in the ovary is likely to exert its effect through leptin receptor found both in granulosa and theca cells of preovulatory follicles. Adiponectin, an adipocytokine, is also involved in maintaining energy balance. Both adiponectin and two of its receptors, AdipoR1 and AdipoR2 are abundantly expressed in the ovarian granulosa and theca cells. Adiponectin is likely to affect gonadotropin or insulin-like growth factor-1 (IGF-1) induced progesterone production from preovulatory follicles.

Ovulation

Ovulation of the largest preovulatory follicle (F1) occurs by rupturing the follicular wall along the stigma with the help of proteolytic enzymes and vasoactive substances. The process is initiated by a surge in plasma LH levels 4–6 h prior to ovulation. An increase in plasma progesterone levels is required for initiating the preovulatory LH surge. Egg-type chickens ovulate every 24–28 h with a temporal rhythmicity that is regulated by expression of clock genes located in granulosa cells, liver, and hypothalamus. LH is thought to be the mechanistic link that integrates the hypothalamic circadian pacemaker with ovarian clock genes and therefore timing of ovulation.

Oviduct

Only the left oviduct is developed in the post-hatch chicken. Oviduct is a tubular organ (Fig. 4) consisting of infundibulum, magnum, isthmus, shell gland or uterus, and vagina. Oviduct is innervated by both sympathetic and parasympathetic nervous systems. The infundibular region starts as thin membranous funnel shaped organ that receives the oocyte following ovulation and retains it for 15–30 min. It is also the site where spermatozoa are stored and fertilization occurs. Infundibulum is followed by magnum, a long muscular and highly vascularized organ where the components of egg white (ovalbumin, lysozyme, conalbumin, and avidin) are secreted over a 3 h duration. Isthmus is a narrow tubular structure that is less muscular than magnum. This region secretes inner and outer shell membranes within a transit time of 1–2 h. The shell gland is a thick muscular organ where the soft-shelled egg is retained for 18–26 h at which time the shell gland transports 2.0–2.5 g of calcium from blood circulation to calcify one egg. Such large amounts of calcium are derived from two sources: (1) medullary bone (humerus, femur, and tibia) aided by parathyroid hormone and 1, 25 dihydroxyvitamin D₃; and (2) dietary calcium whose absorption is aided by 1, 25 dihydroxyvitamin D₃. Shell gland and vagina also secrete large quantities of mucin-rich fluid to coat the egg surface to prevent entry of pathogenic organisms into the egg.

Oviposition

Oviposition is the process of expulsion of egg from the shell gland by contracting the myometrium while relaxing abdominal muscles and the sphincter that separates shell gland and vagina. Arginine vasotocin acting via VT1 and VT3 receptors is likely to be involved in the contraction shell gland smooth muscle. The role of mesotocin, the avian homologue of oxytocin, in reproductive functions is unclear as the existence of a functional mesotocin receptor has not been identified. Prostaglandin F_{2α} and prostaglandin E and other factors secreted by the largest preovulatory follicle and/post-ovulatory follicular membrane may also aid in shell gland contraction during oviposition.

Sperm Storage Tubules

Utero vaginal junction contains specialized sperm storage tubules that is lined by a mucosal surface to store spermatozoa for a period of 7–14 days. Upon insemination, the tubules are filled with sperm in a sequential fashion such that the spermatozoa from the latest insemination is released from the tubules first upon every oviposition. The sperm storage tubules lack innervation and smooth muscle for release of spermatozoa. However, hormonal factors such as progesterone may be involved in the release of spermatozoa from sperm storage tubule.

Reproductive Dysfunction

Excessive Follicular Recruitment in Broiler Breeder Hens

Ovarian follicular selection and maturation are extremely coordinated with ovulation occurring nearly every day in egg-type chickens. However, this process is deranged in the broiler breeder parent females leading to multiple follicles being selected simultaneously (Fig. 5). The desired economic traits in broiler chickens are body weight, growth rate, feed conversion efficiency, meat yield, breast muscle yield, livability, and leg strength. Most of the broiler selection traits are negatively correlated with egg production and fertility. Similar to their progenies, the broiler breeder parents are hyperphagic and become obese if provided unlimited access to feed. Consequently, broiler breeder hens lay only 160 eggs/hen during their economically productive life span compared with more than 280 eggs/hen laid by Leghorn hens. Excess feed intake appears to have direct deleterious effects on ovarian follicles. Therefore, broiler breeder hens are fed restricted amount of feed to prevent adiposity. Feeding broiler breeder hens with a diet that provides 30% more than the energy requirement leads to decreased egg production, follicular atresia, and early ovarian regression associated with increased levels of pro-inflammatory molecules such as interleukin 1 β and decreased amounts of phospho-Akt in the hierarchical follicles (Pan *et al.*, 2012). Feed restriction to broiler breeder pullets between 7 and 15 weeks-of-age followed by ad libitum feeding led to improved reproductive performance, although pituitary and plasma LH and FSH concentrations, and median eminence levels of GnRH-I, were not different compared with pullets fed ad libitum (Bruggeman *et al.*, 1998). This raises the possibility that FSH responsiveness in the pre-hierarchical follicles is increased in response to overfeeding in broiler breeder chickens. Inhibin, a hormone secreted predominantly by the granulosa cells of the ovarian follicle, acts as a negative feedback regulator of pituitary FSH secretion. Expression of the inhibin α -subunit and inhibin/activin β A and β B subunits as well the activin type II receptor have been documented in the developing follicles of broiler breeder hen ovaries suggesting a paracrine role for inhibin and activin within the ovary. Active immunization of broiler breeder hens against inhibin was found to increase cumulative number of eggs produced by 9.5% (Satterlee *et al.*, 2002).

Egg-Type Chickens as a Model for Ovarian Cancer

A high proportion (25–40%) of egg-type chicken develops ovarian cancer around 2–4 years of age. Although the cause of spontaneous ovarian cancer in chickens is unknown, incessant ovulation is likely to contribute to the high rate of ovarian cancer incidence in chickens since they ovulate nearly every day. Elevated levels of harmful mutagenic chemicals have been found in the surface epithelium of the preovulatory follicle. Some of the ovarian tumors in chickens are associated with mutations in the *p53* oncosuppressor gene. Ovarian tumor in chickens appears like a large cauliflower-like mass (Fig. 6). In advanced stages of the disease, numerous metastatic tumor nodules could be noticed on the walls of the intestine, peritoneum, and mesentery, and liver. Histological appearance of the chicken ovarian tumor resembles that of commonly found endometriod type of ovarian adenocarcinoma and/or anaplastic ovarian carcinoma in women (Fig. 6). As in women, advanced stages (stage III and IV) of ovarian cancer in chickens are accompanied by accumulation of large volume (0.5–1 L) of ascites. Ovarian cancer cells isolated from ascites

PLOS ONE 8(2), e57582.

were found to be highly invasive in extracellular matrix proteins. In addition, the chicken ovarian cancer cells express several genes and proteins such as E-cadherin that are typically associated with ovarian cancer in women (Tiwari *et al.*, 2013). The chicken model of ovarian cancer is used as a preclinical model of human ovarian tumor (Johnson and Giles, 2013) to evaluate the effectiveness of ovarian cancer prevention strategies.

Avian Reproduction – Overview (Wild Birds)

Tony D Williams, Simon Fraser University, Burnaby, BC, Canada

© 2018 Elsevier Inc. All rights reserved.

Introduction

Domesticated species, especially the chicken, have been selected over centuries for continuous “aseasonal” reproduction with maximum rates of egg production (up to 300 eggs per year), minimum variation in egg size, and little or no post-hatching parental care. In contrast, the ~10,000 species of wild birds generally show seasonal breeding cycles with egg-laying and rearing of young restricted to a particular time of year (often spring and early summer) when environmental conditions (food, temperature) are optimal for successful reproduction. Among- and within-species there is large variation in egg size, clutch size and number of breeding attempts (1–4 broods per year). Furthermore, there is considerable variation in parental care (uniparental, bi-parental) including patterns of incubation behaviour, developmental maturity of chicks at hatching, and post-hatching care (brooding, guarding and/or feeding chicks to independence). Many birds breed first at 12 months of age, the year after they hatch, but some seabirds show long-deferred sexual maturity (up to 12 years).

Male Reproductive System

Male birds have internal, paired testes suspended from the dorsal wall of the body cavity at the top of the kidneys. Testis size varies seasonally with sexual activity, representing as little as 0.005% of body mass in immature or non-breeding males but increasing 500- to 1000-fold during breeding. For example, in the European starling (*Sturnus vulgaris*) testis volume increases gradually from <10 mm³ in late January to 500 mm³ in early April in response to increasing daylength (Fig. 1). Each mature testis consists of thousands of coiled seminiferous tubules containing germ cells, responsible for spermatogenesis, and Sertoli cells, which assist in sperm maturation. Interstitial or Leydig cells secrete steroid hormones (androgens) which control sexual behaviour (song and copulation) and development of some, but not all, secondary sexual characteristics (plumage and bill color). The seminiferous tubules join to form a long epididymis and deferent duct which carries mature sperm in seminal fluid to the cloaca. Sperm are generally short and relatively simple in non-passerines but longer and spiral-shaped in passerines (Jamieson, 2007). The distal end of the deferent duct forms the seminal glomus, a specialized sperm storage accessory structure. During the breeding season the male's cloaca swells forming a cloacal protuberance and in most species copulation and sperm transfer involves simple cloacal contact with the male everting his cloaca into the opening of the female's oviduct. Some ratites (e.g., ostrich) ducks, and geese have a more developed and erectile phallus or pseudopenis though this lacks an internal urethra.

Female Reproductive System

Two bilaterally symmetrical ovaries and oviducts develop in the avian embryo but in nearly all species only those on the left side are functional in adult life (birds of prey, Falconiformes, and the kiwi, *Apteryx* spp., retain two functional ovaries). The ovary is suspended from the dorsal wall of the body cavity near the top of the kidneys and consists of many oocytes embedded in a stroma of connective tissue. Oogenesis is terminated at hatching, at which time the ovary contains >450,000 primary oocytes although as few as 1–20 of these will mature and be laid as eggs depending on the species' breeding strategy and life span. Once oocytes

Fig. 1 Sex-specific differences in timing and rate of seasonal gonadal maturation in male (triangles) and female (circles) European starlings. Asterisk indicates when mature sperm are first produced. Based on data in Dawson, A., 2003. A comparison of the annual cycles in testicular size and moult in captive European starlings *Sturnus vulgaris* during their first and second years. *Journal of Avian Biology* 34, 119–123 and on unpublished data from T. D. Williams.

are selected into the hierarchy of developing follicles (Johnson, 2015) there is a variable phase of rapid yolk development (lasting 3–25 days in different species), with lipid- and protein-rich yolk precursors being taken up from the circulation to form the yolk. Follicle development is therefore characterised by estrogen-dependent hepatic synthesis of vitellogenin and yolk-targeted very low density lipoprotein (VLDL) the latter involving a major shift in the female's lipid metabolism (Williams, 2012). Granulosa and thecal cells proliferate and surround the follicle during oocyte maturation, synthesising and secreting hormones (progesterone, estradiol, growth factors) required for yolk development, oviduct function and control of female sexual behaviour. In contrast to mammals, the female is the heterogametic sex in birds (ZW) and thus determines offspring sex; there has been much interest in putative 'adaptive' sex ratio manipulation of offspring by mothers though the significance of this, and underlying mechanisms, remain poorly resolved (Rutkowska and Badyaev, 2008; Postma *et al.*, 2011).

At ovulation, the fully-developed yolk passes into the oviduct where albumen and shell are added to complete egg formation over about 24 h. The avian oviduct comprises five morphologically and functionally distinct regions. Fertilization occurs in the top section (infundibulum) shortly after ovulation before albumen deposition prevents sperm reaching the oocyte. Most albumen is added in the magnum, shell membranes in the isthmus, and shell and cuticle in the shell gland (over 18–20 h). Egg shells of wild birds can be highly, and variably, pigmented with porphyrins being associated with red and brown egg color and biliverdin giving blue and green coloration. The mechanism(s) determining patterning and egg coloration are still not known although it has been suggested that rotation of the egg in the shell gland might contribute to streaking.

Neuroendocrine Regulation of Gonadal Function

Seasonal cycles of gonadal maturation and regression in wild birds are regulated by the hypothalamic-pituitary-gonadal (HPG) axis (Dawson, 2008; Fig. 2), with the central nervous system and the hypothalamus receiving and integrating sensory information (both environmental and physiological), transducing this into humoral, hormonal signals which regulate gonadal function. Pituitary function is in turn regulated by the rate of secretion of chicken gonadotrophin-releasing hormone-I (cGnRH-I), and gonadotrophin-inhibiting hormone (GnIH). GnRH stimulates synthesis and release of the gonadotrophic hormones, luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary. LH is thought to primarily regulate gonadal steroidogenesis and ovulation, and FSH regulates spermatogenesis and follicle development. In addition to stimulating vitellogenesis and yolk uptake, ovarian steroids affect many other aspects of physiology and behaviors such as aggression, territoriality, nest building, courtship and copulation (Adkins-Regan, 2005) and development of secondary sexual characteristics.

This "top-down" model of control of gonadal function by the hypothalamus and pituitary appears to be appropriate for males, with a primary role for photoperiod, whereby gradually increasing day length in spring is associated with an early and gradual increase in testis size (Fig. 1). Artificial long photoperiods (>13 L) alone are sufficient to stimulate complete testicular maturation, steroidogenesis (albeit with somewhat lower testosterone titers) and spermatogenesis in males of wild birds in captivity, with photo-stimulation elevating plasma LH and FSH levels to those typical of free-living birds. Furthermore, testis development in captive males is very similar or identical to changes seen in free-living birds in response to gradually increasing day length in spring, and rate of testis growth is proportional to artificial photoperiod. In contrast females of most free-living species held in standard

Fig. 2 Organization of the hypothalamic-pituitary-gonadal (HPG) axis, which integrates environmental information and regulates ovary, oviduct, and liver function for vitellogenesis, yolk, and egg formation, and parental care in birds. DA, dopamine; VIP, vasointestinal peptide (see text for other abbreviations).

captive conditions (small cages) will not undergo complete ovarian development: the ovary can develop to the pre-vitellogenic phase but onset of vitellogenesis, yolk formation and egg production is very unusual in captivity (except in large aviaries at low density). Although increasing day length in spring – or artificial long photoperiod in captivity – “switch on” the HPG axis at the hypothalamic and pituitary level in females, with increased GnRH and LH secretion, there is growing evidence for additional, (as yet unidentified) peripheral levels of control in the ovary and/or liver. For example, in female European starlings hypothalamic GnRH, GnIH, and pituitary FSH mRNA are already elevated in March before onset of ovarian development but LH and FSH receptor expression in the ovary does not increase until April with the onset of vitellogenesis (Perfito *et al.*, 2015). In free-living birds there is no gradual increase in ovarian or oviduct size with increasing day length (cf. male development; Fig. 1) and plasma estradiol levels remain low, until there is very rapid gonadal maturation 4–5 days before the first egg is laid (Williams *et al.*, 2004). The standard explanation for these sex-specific differences is that other non-photoc cues (e.g., temperature, social cues) contribute to regulation of ovarian development (see Section Environmental Regulation of Seasonal Reproduction) though the mechanism(s) by which this information is integrated with the HPG axis remain poorly understood (Visser *et al.*, 2010).

Photoperiod also allows most birds to predict in advance the time for termination of breeding, a process called photorefractoriness (Dawson, 2002). This is important since, if laying were to continue until food availability began to decline, young would be in the nest at a time when there is insufficient food to rear them successfully. However, again there are important (and unresolved) sex-specific differences in the timing or pattern of this process at least at the level of the testis and ovary. In males photorefractoriness is marked by rapid testicular regression at the very end of the breeding season and males can only respond to stimulatory long day lengths again after exposure to a period of short day lengths (<8 L) in fall. In females, ovarian and oviduct ‘regression’ (and follicle atresia) occur at the end of each bout of egg-laying, coincident with clutch completion typically early in the breeding season, and repeatedly in multi-brooded species. However, females are still capable of re-laying at this time, i.e., they are not photorefractory in the classic (male) sense.

Environmental Regulation of Seasonal Reproduction

In almost all wild birds breeding is restricted to a particular time of year coincident with a seasonal improvement in environmental conditions required for successful rearing of offspring, e.g., increased food availability, higher temperatures, or increased rainfall (Williams, 2012). Annual cycles of reproduction are most common, with birds in temperate and higher latitudes breeding in spring and early summer. In some tropical-breeding species individual birds can lay in any month of the year, although birds do not breed continuously and many species do have seasonal breeding cycles, albeit cycles not clearly associated with changes in day length but perhaps with cycles of rainfall or food availability (Beebe *et al.*, 2005).

In general, individuals that time breeding such that they have their chicks in the nest when food is most available will breed more successfully (Fig. 3), i.e., they will have higher fitness. Thus, food availability required for offspring growth sets a selective or evolutionary value on timing of breeding, and is the “ultimate factor” explaining *why* birds have evolved to breed when they do. However, before young hatch their parents must undergo extensive physiological and behavioral preparation for breeding, for example, maturation of the reproductive system, finding a nest site and mate, and laying and incubating eggs. These pre-laying events can take 6–13 weeks to complete and often must be initiated well in advance of any seasonal increase in food availability (Fig. 3) so birds must be able to *predict* the onset of their breeding season well in advance which they do using information from environmental cues or “proximate” factors. Proximate factors therefore explain *how* birds time their breeding season. The main proximate factor used by birds to time their breeding season, outside of the tropics, is the annual cycle of day length or photoperiod: since day length varies absolutely predictably each year, increasing day length in spring provides long-term or initial predictive information for timing of breeding. However, since there is usually small-scale, local variation in environmental conditions from year to year, other

Fig. 3 Timing of breeding in blue tits in relation to availability of the bird's caterpillar prey showing that egg-laying is initiated well in advance of the seasonal increase in food availability. Based on data in Gibb, J.A., 1950. The breeding biology of the great and blue titmice. Ibis 92, 507–539.

non-photoc factors, such as temperature, food availability, and social interactions are thought to provide essential supplemental information allowing birds to fine-tune the onset of egg laying itself to local conditions. This overall conceptual framework for environmental control of seasonal reproduction is very long-standing (Murton and Westwood, 1977; Wingfield and Farner, 1993) and provides a reasonable explanation for control of reproduction in males. However, unequivocal experimental evidence for the role of non-photoc cues in free-living or non-domesticated birds is still lacking (e.g., temperature (Schaper *et al.*, 2012), social cues (Cornell *et al.*, 2017)) especially for females in relation to timing of egg-laying (Williams, 2012).

Variation in Breeding Seasonality, and Onset of Sexual Maturation

Most birds breed annually, though some exceptions include sooty terns (*Onychoprion fuscatus*) which breed sub-annually (with a mean period of 9.6 months, Reynolds *et al.*, 2014), king penguins (*Aptenodytes patagonicus*) which breed 2 out of every 3 years on average, and the wandering albatross (*Diomedea exulans*) which breeds biannually. Nevertheless, there is marked variation in age of first breeding. Most small-bodied, short-lived birds (e.g., passerines) breed for the first time in their first spring after hatching, that is, when they are about 1 year old. Other, typically larger, species delay breeding for 1 or more years after hatching and some long-lived species, such as albatrosses and penguins, show long deferred sexual maturation, breeding for the first time at 6–12 years of age. In contrast, a few species can show precocial sexual maturation, for example, the zebra finch (*Taeniopygia guttata*) can breed at around 3 months of age.

The mechanisms underlying timing of sexual maturation in wild birds remain poorly understood although nutritional status, body growth, or age per se do not appear to be important determining factors. In species which first breed at 1 year of age, there is evidence that timing of initial sexual maturation (puberty) is photoperiodically determined. Chicks hatch in a physiological state similar to adult photorefractoriness (termed juvenile refractoriness) ensuring they do not show an immediate response to the stimulatory effects of long day lengths with gonadal maturation in their first summer (as nestlings). Young birds remain photorefractory until the fall, when they become photosensitive due to the effect of short day lengths. Sexual maturation then occurs in response to long day lengths the following spring. In species with long-deferred sexual maturation there is some evidence that younger, pre-breeding birds are physiologically immature, with very low circulating sex steroid and gonadotropin levels even though these birds attend the breeding ground. However, the pituitary and gonads appear fully functional in one-year-old birds (e.g., responding appropriately to treatment with exogenous GnRH or LH). In males, and females of some species (e.g., macaroni penguin, *Eudyptes chrysolophus*), plasma levels of sex steroids and gonad size increase with age but older pre-breeding birds have plasma hormone profiles indistinguishable from those of adult birds one or more years before actual onset of breeding. In other species (e.g., wandering albatross) females appear to have different plasma steroid profiles even in their final pre-breeding year, compared to breeding females, with high progesterone and low estradiol levels and no evidence of follicular maturation. In addition to delayed physiological maturation in some species, there may also be a behavioral or social component to age of first breeding, with several years being required for birds to learn complex sexual displays or courtship rituals.

Eggs, Egg-Laying and Clutch Size

Free-living species show marked inter- and intraspecific variation in egg size and fecundity (clutch size). Egg mass scales with body mass across species, for example, Anna's hummingbird (*Calypte anna*) has a body mass of 4 g and egg mass of 0.5 g, compared with an ostrich (*Struthio camelus*) where body mass and egg mass are 100 and 1.4 kg respectively. Relative egg mass therefore scales negatively with body size (here, 12.5% and 1.4% respectively). Some species, such as blue tits, lay total clutch masses greater than their body mass. Egg size also varies markedly among individuals of the same species or population: the largest eggs laid by individual females within a population are generally at least 50% larger, and sometimes twice as large, as the smallest eggs laid by other individuals and approximately 70% of the total variation in egg size is due to variation between clutches, i.e., among individual females, not within clutches (Christians, 2002). Factors such as age, experience, or body mass, and 'environmental' factors (temperature, food) explain relatively little intraspecific variation in egg-size. There is much smaller, but systematic, variation in egg size within-clutches though this is smaller in precocial species compared with altricial species (0.68% vs. 3.91%), and in passerines is smaller in hole-nesting species compared with open nesting species (3.56% vs. 0.05%; Slagsvold *et al.*, 1984).

Many free-living passerines lay one egg per day and, in some species at least, daily timing of egg-laying is highly synchronous and occurs very soon after sunrise, i.e., there is a strong circadian pattern of oviposition (consistent with the "open period" model, Etches, 1996). Most other non-passerines, and some sub-oscine Passeriforms (e.g., Tyrannidae, Pipridae, Cotingidae) have laying intervals that are typically 2–4 days and the Ancient murrelet lays a 2-egg clutch with a 7-day laying interval. In some species at least it is clear that laying intervals >24 h are associated with longer intervals between initiation of yolk development (follicle recruitment) rather than differences in duration of development of successive yolks.

Despite the marked variation in egg size, there is relatively little evidence to support strong, positive, and especially long-lasting, effects of egg size on offspring growth and survival (Krist, 2011). Egg size is positively correlated with chick mass at hatching, and the primary benefit of larger eggs might be to increase offspring survival in the first few days after hatching. Positive, but weak, correlations between egg size and chick growth can persist for 7–10 days post-hatching but few studies have reported longer lasting effects and then only for certain morphological traits (e.g., wing length) not for body mass in general. Most studies have failed to find an effect of egg size on offspring growth or survival at fledging and, not surprisingly, larger egg size might only confer an advantage to

offspring in situations where resources are relatively low (poor quality habitats, late in the breeding season). In general, therefore, effects of egg size are largest at hatching (effect size, $r=0.4-0.6$) but are lower during the nestling and post-fledging stage ($r \leq 0.2$), and few post-fledging effects of egg size (e.g., on life-history or sexual traits) have been reported (Krist, 2011).

In addition to shell, yolk and albumen many substances, such as steroid, thyroid and protein hormones, antibodies (immunoglobulins), antioxidants and RNA, are transferred from the mother to the egg during egg formation in either the yolk or albumen. These 'minor' egg components have been viewed as potential mediators of "maternal effects": non-genetic contributions to offspring phenotype, by which mothers might "adaptively" adjust the development and the phenotype of their offspring to match prevailing environmental conditions increasing offspring and maternal fitness. Although many short-term effects of maternally-derived egg components on offspring phenotype have been documented (von Engelhardt and Groothuis, 2011) evidence for long-term fitness consequences in free-living birds remains equivocal (Williams and Groothuis (2015); but see Love and Williams (2008) and Duckworth *et al.* (2015)).

Some avian taxa have invariant clutch size, for example, among seabirds, all albatrosses and petrels lay a single-egg clutch, shorebirds (Charadriiformes) have an invariant clutch size of four eggs and most Larids (gulls) lay 3-egg clutches. In contrast marked inter-individual variation in clutch size exists in many species, for example, song sparrows (*Melospiza melodia*), European starlings, and lesser snow geese have modal clutch sizes of 4-eggs, 5-eggs and 4-eggs respectively, but clutch size varies from 2 to 5 eggs, 3–7 eggs, and 1–7 eggs respectively. In blue tits and mallard duck (*Anas platyrhynchos*) with larger modal clutch size of 10-eggs the range of individual clutch sizes is 4–17 eggs and 7–12 eggs respectively. Most species also show strong seasonal patterns of variation in clutch size. Single-brooded species, and some multiple-brooded species such as the Anatidae, Galliformes, and Ralliformes all show a linear, seasonal decline in clutch size (Fig. 4). In contrast, in many other multiple-brooded species clutch size first increases with laying date then declines (Fig. 4). This variation has been related to food availability, predation, and date-dependent reproductive value of offspring (Williams, 2012).

Fig. 4 Seasonal variation in clutch size in (a) single-brooded species (top panel; based on data in Meijer, T., Daan, S., Hall, M., 1990. Parental Care: Incubation and Chick-Rearing

All birds lay external eggs which must be incubated at temperatures $>37^{\circ}\text{C}$ to support embryo development, and most birds use their own body heat for incubation, sitting on eggs in specially constructed nests. In 'continuous incubators' both parents contribute equally to incubation, coordinating and alternating incubation bouts, with a high level ($>90\%$) of nest attendance and frequent, short, off-nest bouts for self-feeding (Deeming, 2002). Other species alternate longer feeding bouts with more prolonged incubation shifts which can range from 1 to 3 days up to 10–20 days, during which incubating birds must fast. Passeriformes and Apodiformes have lower levels ($<75\%$) of nest attentiveness (Deeming, 2002) and this is often associated with uniparental, female-only incubation, with incubating females having to leave the nest intermittently to self-feed. In many passerines with this 'intermittent-incubation' the female's physiological demands of incubation can be further reduced through incubating females being fed by their mates ('courtship feeding'). In contrast to passerines, some uniparental, female-only incubators (e.g., geese, eiders) have very high levels of nest attendance and, consequently, very short and infrequent nest reliefs for feeding, with no male courtship feeding. Incubation can then involve large decreases in body mass up to 30%–40% of initial body mass. Incubation periods last 11 days in small songbirds and up to 60–80 days in some penguins and albatrosses.

There is a continuum of developmental maturity of chicks at hatching, from altricial to precocial (Starck and Ricklefs, 1998). In altricial species, young hatch at a relatively early stage of development, often blind, relatively un-feathered, and unable to thermoregulate. This requires an obligate, but variable, post-hatching period of parental care with nest attendance and brooding of chicks. Chick-rearing periods average 9–20 days in small songbirds, 10–12 weeks in the bald eagle, and 12 months in the wandering albatross. Chicks of altricial species often leave the nest before they are capable of sustained flight and there is a variable period of post-fledging care (which can be longer than the nestling phase). In altricial species parents forage for food for offspring, returning frequently to the nest to feed chicks (central place foraging), as well as defending the nest and young from predators. In small-bodied birds, such as passerines, the number of nest visits made by parents provisioning chicks can be very high, and highly variable, from 300 to 1500 visits/nest/24 h blue tits, and from 0.6 to 4.00 visits/chick/h in European starlings. In contrast, many pelagic seabirds make long foraging trips at sea and return every 1–4 days to feed their chicks with single, very large meals. In precocial species chicks hatch fully-feathered, with a good ability to thermoregulate, they are capable of walking (though not flying), typically leave the nest shortly after hatching, and are often self-feeding. Parental care in precocial species thus mainly involves protecting chicks from predators, and leading them to high-quality foraging areas.

The physiological and hormonal basis of parental care remains poorly understood especially in free-living birds (Adkins-Regan, 2005). Prolactin is likely involved in development and maintenance of incubation behaviour, though perhaps not in clutch size determination (Ryan *et al.*, 2014) or in post-hatching care (Adkins-Regan, 2005). Testosterone has inhibitory effects on male parent care, and glucocorticoids might play a role in mediating foraging behaviour associated with parental care (Angelier and Chastel, 2009).

Costs of Reproduction, Trade-Offs and Carry-Over Effects

'Costs of reproduction' are associated with each breeding stage (egg production, incubation, and chick-rearing). These costs manifest in the short-term, through negative effects of reproductive effort on subsequent breeding stages in the same breeding attempt, in subsequent breeding attempts in the same year (e.g., second broods), or through long-term negative effects on future fecundity and survival many months, or even in the subsequent year, after reproduction (Williams, 2012). There can be direct temporal overlap generating trade-offs between reproduction and other life-history stages such as molt and migration. For example, 'costs' can be mediated by affects of timing of breeding on timing or rate of molt at the end of the breeding season, and resultant feather quality (Dawson *et al.*, 2000). Earlier stages of the annual cycle (wintering, migration, pre-breeding) can also significantly affect reproductive decisions via "carry-over effects" (Wilson *et al.*, 2007). Again, we still know very little about the specific physiological mechanisms underlying trade-offs or carry-over effects, including costs of reproduction (Harrison *et al.*, 2010; Williams, 2012).

Glossary

Acrosome A membrane bound structure which caps spermatozoa. It contains digestive enzymes considered to assist spermatozoa penetrate the outer investments of an ovum.

Anti Mullerian hormone (AMH) A hormone secreted by the testes which inhibits the embryonic Mullerian ducts from developing into the adult female reproductive duct system.

Apocrine gland Sweat glands in the skin which develop from the epidermis or hair follicle.

Capacitation The last process in the maturation of mammalian spermatozoa which provides the capacity to fertilize an ovum.

Cloaca The posterior orifice of embryonic mammals and adults of other vertebrates which serves as the only opening for the digestive, reproductive, and urinary tracts.

Crural system Spurs and associated glands of platypus and echidna. A spur is located on the heel of each hind leg and its gland is located in the loin.

Disulphide bond Strong, covalent bond between adjacent cysteines (amino acids) in a protein. Disulphide bonds provide strength, rigidity and maintain the structure of a protein.

Ductuli efferentes The "efferent ducts" carry spermatozoa from the testis to the ductus epididymidis.

Endothermic Endothermic animals use their own metabolic processes to warm their body.

Epididymis A long, convoluted duct (ductus epididymidis) supported by connective tissue and which carries spermatozoa from the ductuli efferentes to the urethra. In mammals, it is involved in maturing and storing spermatozoa.

Homologous Structures which are considered to have a common genetic (evolutionary) origin.

Major histocompatibility complex (MHC) A group of proteins on the surface of vertebrate cells which recognize and display foreign molecules (eg. from pathogens) so that they can be processed by the appropriate cells (T-cells) of the immune system.

Meiotic chain An alignment of homologous pairs of chromosomes during meiosis.

Protease An enzyme which breaks down protein into amino acids.

Proteome The entire set of proteins expressed by a unit (cell, tissue, organ or organism) at a certain time.

Receptor A protein molecule that receives and responds to a chemical messenger such as a hormone.

Sauropsids Reptiles and birds.

Sex chromosomes Chromosomes involved in determining sex in animals that practice sexual reproduction. Sex chromosomes differ from one another whereas the other chromosomes in diploid cells (autosomes) appear as pairs with the same form.

Sex chromosome inactivation Involves one of the copies of the X chromosome in female mammals being prevented from expressing its code (transcribing). Inactivation of the X chromosome also occurs in the male, but is transient during spermatogenesis.

Sex determination The biological process involved in determining gender in an organism.

Testicond The condition in which testes are retained within the abdominal cavity in vertebrates and do not descend into a scrotum as in most mammals.

Tyrosine phosphorylation A key step in the transfer of a signal, such as a hormone, from the surface of a cell to a target molecule (enzyme). It is an enzyme catalysed process involving the addition of a phosphate group to the amino acid tyrosine on a protein.

Zona pellucida A glycoprotein layer surrounding and supporting a mammalian oocyte, and which is involved in recognition between spermatozoa and ova at fertilization.

Introduction

Reproduction defines monotremes as mammals as they have mammary glands that produce milk which solely supports their developing young until they are independent: at least 60% adult mass for platypus. They are also furred and endothermic. However, their sex chromosomes and method of sex determination are unlike eutherians and marsupials. Like non-mammalian vertebrates, they have a single orifice (the cloaca) for excretory and reproductive functions, their gametes most closely resemble the sauropsids (reptiles and birds), and they lay eggs which are incubated externally. The early work covering monotreme reproduction was reviewed by Griffiths (1978) and then more specifically by Temple-Smith and Grant (2001). Further, there has been a renewed interest in the subject (Grützner *et al.*, 2008) since the platypus genome was sequenced (Warren *et al.*, 2008).

Estimates of the time of divergence of monotremes from eutherian mammals range between 166 and 200 million years ago, making monotremes the oldest surviving mammalian lineage. Only three genera are extant and they are highly specialized animals. Platypus (*Ornithorhynchus anatinus*) are confined to rivers in eastern Australia, and Kangaroo Island, South Australia, where they have been introduced. Short-beaked echidna (*Tachyglossus aculeatus*) occur in almost all Australian habitats and the lowlands of New Guinea. Long-beaked echidnas (*Zaglossus*) are restricted to the highlands of New Guinea (three species have been described) and little is known of them as they are inaccessible to researchers. The extant monotremes have a normal body temperature of 32°C. Platypus are homothermic even in water at 5°C, whilst *Tachyglossus* lower their body temperature during torpor. Both species cope with high temperatures by avoidance behavior.

Male Reproduction

Testes and Sperm Production

The testes of monotremes develop between and caudal to the kidneys as in other vertebrates, but they do not descend into a scrotum as in most mammals. The testicond condition is probably because monotremes do not develop gubernaculum which in scrotal mammals are involved in testicular descent. Consistent with this interpretation is the finding that INSL3 (Insulin like factor 3), which regulates gubernaculum function in scrotal mammals, lacks specificity for its receptor (Lf20606-08-9780128118993: relaxin/insulin-like family peptide receptor 2) in monotremes. The specificity of INSL3 evolved in scrotal mammals by a single point mutation (Park *et al.*, 2008).

Spermatogenesis in monotremes is similar to other mammals. Associations of the stages of germ cell development (cellular associations) only occupy small areas of a seminiferous tubule as in humans and birds, and do not extend for mm along a tubule as in most mammals. According to Daniel Djakiew, the duration of spermatogenesis in *Tachyglossus* is within the range of other mammals: 62 days (4.5 cycles) and a daily sperm production of 6 ± 0.27 million sperm per gram of testis. However, monotremes have a different strategy of sperm production than most scrotal mammals: they produce spermatozoa at a greater rate per testis and are less dependent on storing them available for mating. Monotreme testes increase in size with age and become larger, relative to body mass, than could be comfortably carried in the scrotal position. Consequently, sperm production per testis in monotremes is greater than in scrotal mammals. For example, estimates of the ratio of testes mass to body mass are: 1.74%, 1.97%, 0.006%, 0.67%, 0.91% and 0.54% respectively for platypus, *Tachyglossus*, humans, rats, rams and tammar wallabies. The high rate of sperm production in monotremes is associated with the storage (in the cauda epididymidis) of fewer sperm available for mating: only 25% of extragonadal sperm compared to about 75% in scrotal mammals like the rat and ram.

Monotreme spermatozoa differ from other mammals in that their nuclei are vermiform and cylindrical like sauropsids and they are arranged in a helical shape. Michael Bedford recognized that they are less rigid than sperm from other mammals and related this to the relative thinness of the monotreme zona pellucida compared to the ova of other mammals. Monotreme sperm also have no post-acrosomal sheath over the nucleus as in eutherian sperm, and they have no striated columns in the neck region or coarse fibers supporting the principal piece. Also, the fibrous sheath supporting the principal piece of monotreme sperm is spiraled whereas in eutherian sperm it has longitudinally oriented connections between adjacent rings. Further, there is no disulphide bonding in the nucleus due to the absence of cysteine residues in the protamine-1 sequences of monotremes. The acrosome is small and mainly limited to the rostral surface of the nucleus and platypus lack the genome for testis-specific proteases which are considered to play important functions in degrading the zona pellucida of eutherians during fertilization. Nevertheless, orthologs of many of the sperm membrane proteins related to fertilization in other mammals are present in the platypus genome. They include the following genes for putative zona pellucida receptors and proteins implicated in sperm-oolemmal fusion in eutherian mammals: zona pellucida binding protein (*Zpbp*, *Sp38*), zona pellucida binding protein 2 (*Zpbp2*), zona pellucida sperm-binding protein 3 receptor (*Zp3r*; *Sp56*), hyaluronoglucosaminidase 5 (*Hyal5*; *Spam1*; *Ph20*), a disintegrin and metalloproteinase domain 1a (*Fertilin alpha*), sperm autoantigenic protein 17 (*Spa17*; *Sp17*), milk fat globule-EGF factor 8 protein (*Mfge8*; *Sed1*), UDP-Gal: betaGlcNAc beta 1,4-galactosyltransferase (*B4galt1*), fucosyltransferase 5(alpha (1,3) fucosyltransferase) (*Fut5*), mannosidase 2, alpha B2 (*Man2b2*) and izumo sperm-egg fusion 1 (*Izumo1*).

Excurrent Ducts

Sperm are transported from the testis by the ductuli efferentes which join the ductus epididymidis (epididymis) which then connects to the urethra (Fig. 1). The monotreme epididymis performs more functions than the epididymis of sauropsids. Relative to animal mass the duct is longer than sauropsids and as long as other mammals. Also, unlike the sauropsids, it is segmented, but only into an initial and terminal segment (caput and cauda epididymidis). Significantly, the epididymal epithelium of eutherians and marsupials is differentiated into about 6 segments indicating that their sperm are exposed to more opportunities for modification. The initial segment of *Tachyglossus* is more than 96% the length of the ductus epididymidis and the ultrastructure of the epithelium does not vary along the duct. It possesses features unique to the initial segment of the mammalian epididymis: epithelial structure and dependence on luminal fluid from the testis. This is significant as the initial segment plays an essential role in post-testicular sperm maturation in eutherians and marsupials (Jones *et al.*, 1987) and is also associated with post-testicular sperm maturation changes in monotremes: migration and loss of the cytoplasmic droplet along the middle piece and development of motility. The terminal segment of the epididymis partly compensates for its short length by possessing mucosa-forming folds, or villi, which

Fig. 1 Diagram of the male reproductive system of *Tachyglossus*. The gross anatomy of the testis and epididymis are shown on the left side and a diagrammatic representation of the arrangement of the sperm ducts is shown on the right side.

ensure that the relatively wide lumen is faced by a considerable area of epithelium. Djakiew estimated that it takes about 14 days for sperm to pass through the excurrent ducts of the testes of *Tachyglossus*: 29 min through the ductuli efferentes, and respectively 10 and 4 days to pass through the initial and terminal segments of the epididymis.

Work on the *Tachyglossus* showed that, as in other mammals, sperm are dilute when they leave the testes and that most of the accompanying fluid and protein is reabsorbed in the ductuli efferentes (74% and 46% respectively). The initial segment of the epididymis reabsorbs 83% of the fluid that enters and it secretes protein, the concentration of protein in the luminal fluid increasing from 4.9 to 58.8 $\mu\text{g}/\mu\text{l}$. The terminal segment also secretes protein, but the luminal concentration is only 39.8 $\mu\text{g}/\mu\text{l}$, a reduction due to either binding to sperm or reabsorption from the lumen. Jean-Louis Dacheux showed that hundreds of proteins are secreted into the initial segment and there is no variation along the segment in the composition of secreted proteins. Few of the epididymal proteins identified in eutherian mammals are present in the platypus epididymal proteome in which more than 50% of the total protein present consists of 3 proteins which have never been identified in epididymal secretions of any other mammal (PXN-FBPL, SPARC and E-OR20). However, SPARC (secreted protein, acidic and rich in cysteine or osteonectin) has been identified in mouse epididymal tissue (Sage *et al.*, 1989). Further, although E-OR20 (epididymal ornithorhynchus protein 20 kDa) is a new lipocalin, it is homologous with lipocalins identified in the epididymides of other mammals and a lizard (*Lacerta vivipara*).

The changes in protein concentration along the epididymis are associated with the formation of sperm bundles (Fig. 2) which are unlike any sperm association described in vertebrates. In histological sections the bundle formation is obvious as sperm leave the initial segment. One hundred sperm have been counted in transmission electron micrographs of *Tachyglossus* sperm bundles; the rostral ends of sperm heads are embedded in an electron dense material and more distally the heads are supported by less dense material. Brett Nixon and colleagues identified the supporting material as SPARC in sperm bundles of the platypus and *Tachyglossus*.

Sperm Capacitation

Platypus and *Tachyglossus* sperm bundles have a forward velocity about 3-times that of individual sperm when diluted and incubated *in vitro*. Sperm within bundles will not undergo an acrosome reaction or bind to the perivitelline membrane of domestic hen oocytes (which share homology with the platypus zona pellucida (see below)). Work on *Tachyglossus* showed that epididymal or ejaculated sperm could achieve these capacities, but only when they dispersed from the bundles after a period of incubation *in vitro* for about 1 h or more. In this respect, they conform to the original descriptions, by CR Austin and MC Chang, of sperm capacitation in mammals. However, the process is not the same as in eutherians and marsupials in which capacitation also involves significant membrane changes and activation of a cAMP mediated signaling pathway that promotes tyrosine phosphorylation of multiple sperm proteins. Consequently, it is interpreted that monotremes exhibit an early form of sperm capacitation.

Accessory Glands of Reproduction

Unlike sauropsids, monotremes have a prostate gland (like all mammals) and paired bulbourethral (Cowper's) glands, and there is evidence that these glands are androgen dependent in the platypus and *Tachyglossus*. The prostate glands are the disseminate type and not sufficiently large to be obvious macroscopically. Also, there is little epithelium in the Cowper's glands. Nevertheless,

Fig. 2 Scanning electron micrograph of sperm bundles from the cauda epididymidis of *Tachyglossus*. Reproduced with permission from Djakiew, D., Jones, R.C., 1983. Sperm maturation, fluid transport and secretion and absorption of protein in the epididymis of the echidna, *Tachyglossus aculeatus*. *J. Reprod. Fertil.* 68, 445–456.

a domesticated *Tachyglossus* male trained for semen collection emitted a clear viscous fluid from the penis prior to emitting semen; it is unknown if there is mixing of these (presumably) accessory gland secretions and epididymal semen.

Penis

The penis of the platypus and *Tachyglossus* is normally retracted into a preputial sac in the ventral cloaca and when erect it protrudes through the cloaca. The urethra opens at the base of the penis so that only semen passes through the penis, while urine is normally excreted directly through the cloaca. The glans penis is bifid, as in marsupials, and the structure of the glands differs between species. Steve Johnson described an unusual ejaculatory mechanism in *Tachyglossus* in which alternate sides of the glans penis deliver successive ejaculations. While this appears unique among mammals, it is similar to the use of hemipenes in squamate reptiles.

Crural System

Male monotremes develop spurs on the heels of their back feet and each spur is connected to a secretory (crural) gland in the groin. In both platypus and *Tachyglossus* the glands are active during the breeding season, but they differ between genera in size and purpose. Platypus spurs are large in adults (25–30 mm long) and their glands produce a venom which can kill a small dog or cause humans excruciating pain when spurred. The venom contains a complex mixture of peptides (Wong *et al.*, 2013) including defensin-like peptides, C-type natriuretic peptides which can release histamine and effect calcium influx, hyaluronidase, amide oxidase, protease inhibitor, proteins associated with stress response and immune molecules. The spurs are probably involved in inter-male rivalry, either to establish territory or in competing for females. The venom is not lethal to platypus as they can degrade it.

Tachyglossus males have short spurs (about 5 mm long) and lack the ability to erect them. The transcriptome of the gland is quite different to the platypus and has functional terms associated with steroidal and fatty acid production. It is more likely involved in scent marking than overt aggressive behavior.

Female Reproduction

Reproductive Ducts

Both ovaries are functional in *Tachyglossus*, but only the left is functional in the platypus (Fig. 3) as in many sauropsids. The right platypus ovary remains embryonic retaining numerous primary follicles. As in sauropsids and virgin marsupials the female reproductive ducts of monotremes are paired and individually join the urogenital sinus. The latter communicates with the cloaca which also receives the rectum. Each duct is differentiated into an oviduct and uterus and, as in other mammals the junction between the uterus and oviduct contains numerous tubular glands. Peter Temple-Smith and Tom Grant consider that insemination is probably intrauterine.

Fig. 3 Female reproductive tract of the platypus showing that both uteri are well developed, but only the left ovary is developed. The inserts at the top of the figure show the ovaries dissected from the tract. Reproduced with permission from Grutzner, F, Nixon, B., Jones, R.C., 2008. Reproductive biology in egg-laying mammals. *Sexual Development* 2, 115–127.

Breeding and Early Development

Monotremes are solitary animals, and seasonal breeders with mating around July to August with some variation according to latitude. There have been no successful attempts to determine the endocrine control of the estrous cycle, although a study of seasonality suggested that the control resembles the avian rather than mammalian model.

At ovulation, the ovum is small (4 mm diameter) in monotremes compared to sauropsids. Unlike other mammals, monotreme ova contains yolk, but much less yolk than in sauropsid eggs. As at least 3 vitellogenin genes have been identified in the platypus genome, it is interpreted that monotreme yolk probably consists of glycoproteins derived from the vitellogenin precursor proteins, as in the sauropsids. The monotreme ovum is contained by the vitelline membrane within a very thin zona pellucida and a tunic of 2 layers of columnar, follicular cells. Oviduct secretions form additional layers. Two layers of albumen are formed, the upper two-thirds of the oviducts secreting the densest layer. A basal layer of the shell membrane is formed in the distal third of the oviduct and a second, denser layer, is formed in the proximal uterus. Uterine glands in the body of the uterus secrete a nutritive fluid which is absorbed by the egg. A third uterine secretion is the precursor of the protective layer of the shell which remains flexible and porous. The egg has a diameter of 14–15 mm when laid.

Fertilization occurs prior to or during the formation of the albumen layer and the second meiotic division is completed when the egg enters the uterus. Sperm-egg recognition probably involves the zona pellucida proteins as in other mammals. The 4 proteins of the human zona (Zp1, Zp2 (Zpa), Zp3 (Zpc), and ZP4/B) possess single orthologs encoded in the platypus with a high level of homology (approximately 40–50% identity on the amino acid level). They also display a high level of homology with proteins in the chicken inner perivitelline membrane which is analogous to the mammalian zona pellucida. However, whilst the avian membrane consists of 3 major components (homologs of the Zp1 and Zp3 families and a unique, phylogenetically distinct protein, ZPD) the ZPD is absent in the platypus and eutherian mammals.

Gestation, from mating to egg laying, is 15–20 days in platypus and 23 ± 3 days in *Tachyglossus*. In the uterus, the egg undergoes nuclear conjugation and incomplete meroblastic cleavage as in the sauropsids. When the egg is laid, the embryo has 19–20 pairs of somites within a parchment like shell. The platypus normally lays 2 eggs which it incubates in a sealed “birthing” burrow and *Tachyglossus* lays 1 egg which it retains in a “pouch” formed as a depression in the belly. The eggs are incubated for about 10 days and the young are born about 15 mm long. Platypus young are nursed within the birthing burrow until they emerge 121–126 days after hatching. *Tachyglossus* young are carried in the pouch for 45–55 days then kept in a burrow until weaning 170–195 days after hatching. Brian Green and colleagues showed that the rate of growth of *Tachyglossus* young is as fast as mammals like the rabbit. However, the duration of lactation of *Tachyglossus* varies between habitats. For example, even though the masses of *Tachyglossus* are much the same at weaning, Kangaroo Island young are about 60 days older than Tasmanian young (Morrow *et al.*, 2009).

Lactation

Mammary glands develop under the dermis on both sides of the abdomen, but there are no nipples in monotremes, the milk being ejected onto the surface of the hairy skin. Olav Oftedal suggested that the glands may have evolved from ancestral apocrine-like glands which provided moisture, and possibly other substances, to protect the porous eggs during incubation. Although the Hoxd genes involved in mammary gland development in eutherians and marsupials are present in the platypus genome, a sequence of the TgNCS39 transgene (named mammary bud regulatory element, MBRE) which is responsible for activating *Hoxd9* is conserved only in eutherians and marsupials and does not exist in the platypus (Schep *et al.*, 2016).

Mike Augée and collaborators found that *Tachyglossus* initially secretes dilute milk containing 1.3% fat, 7.9% protein and 2.9% carbohydrate whereas mature milk is very concentrated containing 31% fat, 12.4% protein and 2.8% carbohydrate. The fat concentration in adult milk is within the mammalian range, but platypus milk contains considerable polyunsaturated fatty acid whilst *Tachyglossus* milk contains little. The carbohydrate differs from other mammals: half the carbohydrate in platypus milk is difucosyllactose whilst *Tachyglossus* milk mainly contains sialyl- and fucosyllactose. Gene expression of platypus milk proteins is 50% β -lactoglobulin (whey protein) and 30% calcium binding casein; echidna milk contains a higher content of whey proteins than platypus milk. Casein genes are clustered tightly together in the platypus genome and contain recently duplicated β -casein matrix protein genes which are thought to have evolved by duplication of enamel matrix protein, either enamelin or ameloblastin.

Chromosomes and Sex Determination

Monotremes feature a remarkably complex sex chromosome system which is homologous to the sex chromosomes of birds rather than other mammals. The sex determination gene SRY of other mammals is absent in monotremes and Sox3 (from which Sry evolved) is located on platypus autosome 6 (Grützner *et al.*, 2004; Veyrunes *et al.*, 2008). A Y chromosome specific copy of the evolutionarily conserved Anti Mullerian Hormone Gene (AMH) has been discovered on platypus Y5 which is currently considered a candidate sex determination gene in monotremes (Cortez *et al.*, 2014).

Platypus have 5 pairs of X chromosomes in females and 5 X and 5 Y chromosomes in males (Grützner *et al.*, 2004; Murtagh, 1977). There is no homology between platypus sex chromosomes and the eutherian X which is largely homologous with the platypus autosome (Veyrunes *et al.*, 2008). The sex chromosomes of male platypus are segregated into sperm with either 5X or 5Y chromosomes. This segregation is mediated by the 10 sex chromosomes assembling as a chain at the first meiotic division via 9 pseudoautosomal regions. The order and timing of chromosome pairing is remarkably well regulated. In contrast to other mammals monotremes lack meiotic sex chromosome inactivation in male meiotic cells (Daish *et al.*, 2015) and X chromosome inactivation in female somatic cells (Julien *et al.*, 2012). The chromosomes are distributed non-randomly in the sperm nucleus as in other mammals and unlike the random distribution in avian sperm. Genes in the sex chromosomes differ from other mammals showing extensive homology with the chicken Z chromosomes as well as a number of autosomes (Grützner *et al.*, 2004; Veyrunes *et al.*, 2008).

Tachyglossus has 5 pairs of X chromosomes in females and 5 X and 4 Y chromosomes in males. The meiotic chain of the 9 sex chromosomes is similar to the platypus, and most chromosomes of both species are homologous. The only exceptions are platypus sex chromosomes Y3-X4 and parts of Y4 which show homology with *Tachyglossus* chromosome 27. The reason why *Tachyglossus* has one less Y chromosome than the platypus is because platypus Y5 has been trans-located to Y3 in *Tachyglossus*. Further, a demonstration of significant differences in the distribution of MHC genes (major histocompatibility complex) in the chromosomes of platypus and *Tachyglossus* indicates that the order of chromosomes in the meiotic chain differs between species (Rens *et al.*, 2007). This means that there have been ongoing changes to the meiotic chain after the monotremes diverged from the mammalian lineage.

Discussion

It is concluded that reproduction in monotremes involves characteristics of sauropsids, mammals and some unique characteristics. Whilst their sex chromosome system is homologous to the sex chromosomes of birds rather than other mammals, they have fully adopted lactation, a strategy of maternal care that characterizes mammals. Like marsupials, monotremes are dependent on lactation from an earlier stage of development than eutherian mammals and (their eggs) spend only a brief period *in utero*. However, the protection afforded by the monotreme egg shell precludes the apparent need of eutherians and marsupials for the ovum to have a thick zona pellucida to support early development. Consequently, according to Michael Bedford monotremes have retained sauropsid-like spermatozoa which lack the rigidity and forward motility that eutherian and marsupial sperm require to penetrate the thicker zona. On the other hand, the stiffened structure of eutherian and marsupial spermatozoa may be an adaptation in response to competition between males to achieve paternity (sperm competition). In this respect, sperm bundle formation by monotremes also increases the rate and strength of forward motility. It is also perhaps noteworthy that sperm bundle formation has the hallmarks of capacitation of eutherian and marsupial spermatozoa (see above). However, this association requires a better understanding of the biological significance of sperm capacitation.

Glossary

Altricial A condition describing young that are relatively underdeveloped at birth, although some features needed for survival may be more advanced.

Apomorphic A specialized (or derived) trait or character that is unique to a group or species.

Blastocyst An early stage of mammalian development where the embryo is a hollow ball of around 100 cells, reached before implantation or expansion.

Diapause A regulated transient delay in embryonic development, usually at the blastocyst stage.

Macropodid ‘big foot’ A member of the kangaroo and wallaby family of marsupials.

Nidifugous Leaving the nest shortly after hatching.

Nidicolous Remaining in the nest shortly for some time after hatching.

Oviparous Egg laying.

Plesiomorphic An evolutionary trait or character state that is homologous within a particular taxon but is not unique to members of that group.

Post partum oestrus The oestrus that occurs immediately after giving birth.

Semelparity A reproductive pattern in which the females normally only give birth once in their lifetime.

Synapomorphic A shared derived character or trait state that distinguishes a clade from other organisms.

Therian mammals Comprises the two viviparous groups of mammals, the marsupials and the eutherians.

Viviparous Live-bearing.

Introduction

The three groups of mammals – the monotremes, the marsupials and eutherians – primarily differ from one another by their reproduction and the anatomy of their reproductive tracts (Asdell, 1946; Tyndale-Biscoe and Renfree, 1987; Hayssen *et al.*, 1985). There are four species of monotreme, all of which are oviparous (Griffiths, 1978), whereas the 338 or more living species of marsupial all give birth to small, under-developed young after a short gestation supported by a placenta, and most species complete their development after birth within their mother's pouch during the extended lactational period (Tyndale-Biscoe and Renfree, 1987). There is considerable variation in the modes of reproduction amongst the 5000 or so eutherian mammals, with gestations ranging from 2 weeks to 2 years. However, the characteristic that unites all mammals is their ability to lactate and provide milk to support the growth and development of their young.

The reproductive processes of the three major groups of mammals have many similarities (Table 1). Fertilisation is internal, and even in the egg-laying monotremes there is placental exchange and development in utero. In the ovary, the Graafian follicles, functional corpora lutea have similar anatomy and functions. The early embryos begin as bilaminar blastocysts supported by uterine secretions and all have a yolk sac placenta, mammary glands, and lactate. Although monotremes retain some ancestral characters (e.g., egg laying), which show an early divergence from the stock leading to therian mammals, namely the marsupials and the eutherians. Marsupials and eutherians arose from a common ancestral group and are not a derivation of one from the other (Fig. 1). The basic mode of mammalian reproduction originated with the first small nocturnal insectivorous mammals in the Triassic and remained almost unchanged until the late Mesozoic era when mammals started to radiate to fill new habitats and ecological niches. Increasing body size imposed greater physiological and metabolic requirement that provided new selective pressures on reproductive strategies.

Reproductive Strategies

Reproduction in mammals is defined by lactation, which provides the young with nutrition following intra-uterine development. The durations of gestation and lactation are variable. The shortest gestation occurs in marsupials, with a 12.5 day pregnancy in the bandicoot, a peramelid marsupial, to the longest in the African and Asian elephants with 22 months. The monotremes, the echidnas and platypus, have a 22–23 day intra-uterine phase, with a 10 day incubation period within the egg before hatching. Lactation ranges from the ultra-short, 3–5 days as in the hooded seal, to the longest, as in years in whales, elephants and humans. The smallest mammal at birth is the marsupial honey possum, whose newborn young weigh less than 5 mg. The largest mammals at birth are the whales and elephants (2000 kg in the blue whale and around 100 kg in elephants) (Fig. 2).

Table 1 A comparison of reproductive characters amongst the three groups of living mammals

Character	Monotremes	Marsupials	Eutherians
1. Bulbo-urethral glands	Present	Present	Present
2. Prostate gland	Present, disseminate	Present, disseminate	Present
3. Seminal vesicles	Absent	Absent	Present
4. Glans penis	Bifid	Bifid or single	Single
5. Scrotum	Absent	Pre-penial	Pre- or post-penial
6. Testes	Abdominal	Inguinal or scrotal	Abdominal, inguinal, or scrotal
7. Testicular blood supply	Simple	Rete mirabile	Pampiniform plexus
8. Sperm head	Long, fusiform	Short	Short
9. Ureter's entry	Urogenital sinus, dorsal	Bladder, ventromedial	Bladder, ventrolateral
10. Endometrium	Secretory	Secretory	Secretory
11. Ovarian follicles	No antrum, liquor folliculi	Antral, liquor folliculi	Antral, liquor folliculi (no antrum in some species)
12. Corpora lutea	Secretory, autonomous	Secretory, autonomous	Secretory, pituitary or placenta dependent
13. Ovum	Large, yolk-filled	Small, yolk extrusion	Very small, no yolk
14. Cleavage	Meroblastic to blastocyst	Holoblastic to blastocyst	Holoblastic to morula (or blastocyst)
15. Bilaminar blastocyst with trophoblast	Present	Present	Present
16. Muroid coat	Present	Present	Present in few, absent in most
17. Shell coat	Present	Present	Absent
18. Shell	Present	Absent	Absent
19. Embryo formation	From outer layers	From outer layers	Inner cell mass in most
20. Vascularized yolk sac	Present in all	Present in all	Present in some
21. Vascularized chorioallantois	Present	Absent (except Peramelidae)	Present in all
22. Invasive villous placenta	Absent	Absent (except Peramelidae)	Present in all
23. Endocrine function of placenta	Unknown	Steroidogenesis slight; LH, PRL, RXN, GH, and prostaglandin, production	Multiple hormones
24. Immunoprotection of fetus	Unknown	Present	Present
25. Delivery of young	Altricial from egg	Altricial from uterus	Altricial to precocial from uterus
26. Hair and sweat glands	Present	Present	Present
27. Mammary gland, alveolar, and myoepithelial cells	Present	Present	Present
28. Mammary hairs	Present	Present	Absent
29. Mammary anlagen	Areola patches	Areola patches	Mammary lines
30. Teats	Present	Present	Present
31. Mammary glands in males	Absent	Absent	Present
32. Crural spurs and glands	Absent	Absent	Absent
33. Epipubic bones	Present	Present	Absent
34. Pouch	Present/absent	Present/absent	Absent
35. Lactation	Long duration	Long duration	Short duration
36. Milk composition	Major changes through lactation	Major changes through lactation	Minor changes through lactation

Source: Adapted and updated from Tyndale-Biscoe, C.H., Renfree, M.B., 1987. Reproductive Physiology of Marsupials. Cambridge University Press.

All mammals have a high level of parental investment in their young depending on the size and degree of maturation at birth (Derrickson, 1992; Langer, 2008). Some young are born immature and hairless, like most monotremes and marsupials in which the altricial (highly immature and relatively undeveloped) young are only around 0.10% of maternal body weight to many eutherian mammals in which the investment is 15% or more of maternal weight. Exceptions are bears, for example, the giant panda that delivers altricial young that are only 0.1% of maternal body weight and the brown bear whose young is only 0.4% of its mother's weight (Fig. 3). In higher primates including humans, despite their large size at birth, the young are secondarily altricial and need extended parental care extending well beyond lactation.

Comparative Anatomy of the Female Reproductive System

In all mammals the gonad originates as a thickening on the side of the mesonephros. The internal reproductive system develops from the paired Wolffian and Mullerian ducts in the early embryo. The Mullerian duct, is the precursor of the female duct system and regresses in males. In females, the Mullerian duct differentiates to form the oviduct, uterus, cervix and upper vagina, and the

Fig. 1 Evolutionary timeline of the evolution of maternal-fetal exchange from the uterus, oviparity (monotremes) and viviparity (therians), lactation and teat development. Modified from Renfree, M.B., Hore, T.A., Shaw, G., Graves, J.A.M., Pask, A.J., 2009. Evolution of genomic imprinting: Insights from marsupials and monotremes. *Annual Review of Genomics and Human Genetics* 10, 241–262.

Wolffian duct regresses. Despite these common features, the three mammalian groups are also distinguished by their reproductive anatomy. In the monotremes, the ureters never make contact with the bladder, but instead urine reaches the bladder via the urogenital sinus for storage. In marsupials the ureters pass between the genital ducts; while in eutherians the ureters develop lateral to the genital ducts. This difference is established early in fetal development. In female eutherian mammals the paired embryonic Müllerian ducts fuse caudally to form a paired oviducts leading to a single vagina and a single uterus with single cervix (Fig. 4). This

Fig. 2 Relationship between maternal weight and total newborn litter weight. The average birth weight of individual young (5% of maternal weight) is shown as broken line. Newborn individuals (● -eutherians; □): marsupials and litter weight (○) shown for a range of species. Modified from Land, R.B., 1984. *Genetics and reproduction*. second ed. In: Austin, C.R., Short, R.V., (Eds.), *Reproductive Fitness; Reproduction in Mammals*, vol. 4. CUP.

Fig. 3 Maternal investment between mammalian groups. The mass of marsupial and monotreme neonates relative to their mother (0.12% and 0.08% respectively) is much smaller than eutherian neonates (15%) (Hayssen *et al.*, 1985). Despite this, the total mass of monotreme litters at weaning relative to the mothers mass is around 50% (calculated from echidna data reported in Griffiths (1978)). This proportion is similar for marsupial (55%) and eutherian mammals (59%) of comparable size. Thus, marsupials and monotremes rely much more heavily upon lactation for nourishment of young than eutherians do. Modified from Renfree, M.B., Hore, T.A., Shaw, G., Graves, J.A.M., Pask, A.J., 2009. Evolution of genomic imprinting: Insights from marsupials and monotremes. *Annual Review of Genomics and Human Genetics* 10, 241–262.

Fig. 4 The relationships of the excretory and genital ducts in marsupials (top), monotremes (center) and eutherians (bottom). The monotreme condition is a plesiomorphic amniotic condition. Note that in this example the right ovary is non-functional, as in the platypus. The ureters open into the urogenital sinus directly opposite the opening of the bladder, whereas in the synapomorphic therian condition the ureters, while taking either the medial (marsupial) or lateral (eutherian) route, open directly into the bladder. Modified from Renfree, M.B., 1993. Ontogeny, genetic control and phylogeny of female reproduction in monotreme and therian mammals. In: Szalay, F.S., Novacek, J.J., McKenna, M.C., (Eds.), *Mammal Phylogeny*. New York: Springer-Verlag, pp. 4–20.

cannot happen in marsupials because the ureters are in the way, so they form two lateral vaginae, and two completely separate uteri with separate cervixes. Whilst most mammals have paired ovaries connected via paired oviducts, in one monotreme, the platypus, only the left ovary is functional.

The mammalian ovary consists of somatic and germ cells. The primordial germ cells originate outside the embryo body and migrate to the gonadal ridges. During migration and in the ovary they proliferate mitotically, and eventually become enclosed in somatic cells to form primordial follicles. Female germ cells enter meiotic arrest before formation of primordial follicles and remain dormant until after puberty. After puberty individual germ cells reactivate over the reproductive life cycle. As reactivated follicles grow, they secrete increasing amounts of oestrogens which prime the reproductive tract and induce oestrus (mating behaviour). After ovulation the follicle transforms into a corpus luteum secreting progesterone, a hormone essential to maintain pregnancy. Thus female reproduction is characterised by cyclic hormonal changes caused by this ovarian cycle. In some species, such as humans, the follicular and luteal phases are well separated and last about 14 days each (Fig. 5). In others, such as sheep, follicular growth occurs in waves during the late luteal phase so that by the time the corpus luteum regresses after about 16–18 days follicles are nearly ready for ovulation so the follicular phase before ovulation is short – about 4 days. Mice and rats have ultra-short cycles of 4–5 days, with a truncated luteal phase unless the females mate, inducing a surge of prolactin that supports formation of progesterone secreting corpus luteum.

Towards the end of the follicular phase, elevated oestrogens act in the brain to induce oestrous behaviour, so that mating normally occurs only around the time of ovulation. A notable exception is the human and some other higher primates, where mating behaviour in females may occur at any stage of the cycle.

Ovulation in many species is spontaneous as a result of an LH surge induced by the elevated oestrogen levels produced by mature follicles. Some species, such as koalas, cats, rabbits, ferrets and camels, are induced ovulators. In these a neuroendocrine reflex induced by mating provides the trigger for the ovulation-inducing LH surge.

Fig. 5 The mammalian oestrous cycle. In humans, the follicular and luteal phases are well separated and last about 14 days each. The sheep oestrous cycle has a sharp peak of oestrogen during the short follicular phase of around 5 days which immediately precedes behavioural oestrus (green bars). This is followed by a longer luteal phase of about 20 days supported by the progesterone-secreting corpus luteum. Luteolysis occurs concomitantly with the rise in oestrogen for the follicles in the next cycle. Mice and rats have ultra-short cycles of 4–5 days, with a truncated luteal phase unless the females mate, inducing a surge of prolactin that supports formation of progesterone-secreting corpus luteum.

Pregnancy

After ovulation the released egg passes into the oviduct, where fertilisation may occur if mating has happened. After fertilisation the cleaving zygote passes into the uterus. Once there, an embryo-uterine dialogue begins. In many species the uterine lining reacts to the presence of the embryo by complex patterns of cell growth and differentiation mediated by inflammatory cytokines. This is a decidual reaction that establishes appropriate conditions for subsequent embryonic development. Other species, such as marsupials, establish pregnancy without a decidual reaction. As the embryo grows it establishes a placenta that mediates exchange of nutrients, gases and wastes, and regulates maternal physiology through specific hormone production. All mammals have a chorio-vitelline (yolk sac) placenta but in eutherians it is supplanted by a chorioallantoic (allantoic) placenta. In monotremes, the 3 mm fertilised egg undergoes significant intra-uterine development supported by choriovitelline and chorioallantoic transfer to about the 17 somite stage and a diameter of about 17 mm when the egg is laid, after which development is achieved entirely on resources in the egg until hatching and the start of suckling. Marsupials give birth to tiny young after a short gestation, supported by a choriovitelline placenta. Only a few marsupials, such as bandicoots, develop a short-lived chorioallantoic placenta in the last days of pregnancy. In most eutherians the choriovitelline placenta is functional before a chorioallantoic placenta develops and becomes the primary placental organ. In mice, the choriovitelline placenta becomes inverted and is the site of transfer of immunoglobulins to the fetus.

In eutherian mammals pregnancy is longer than the oestrous cycle. If pregnancy is established the life of the corpus luteum is extended to provide the progesterone needed to maintain a receptive and secretory endometrium essential for pregnancy. In marsupials the length of the oestrous cycle is around one month, and longer than gestation length, so extension of luteal life is not observed in pregnant females. Much less is known about the monotreme reproductive cycle. Reliable gestation periods of about 21 days have been recorded for the short beaked echidna. After oviposition, the egg is held in the pouch for about 10.5 days incubation before hatching occurs.

Pregnancy and lactation occupy very different relative periods of time during mammalian reproduction, depending on the reproductive strategy of each group (Fig. 6). In eutherian mammals, pregnancy is relatively long, and the young of most at delivery, whilst variable among species, are relatively mature in contrast to the marsupials and monotremes that deliver highly altricial young that complete their development in the pouch or nest, dependent of lactation (see below). Marsupials have effectively traded the umbilical cord for the teat.

Diapause

About 130 species of mammal have a suspension of embryonic development at the blastocyst stage known as embryonic diapause. Diapause allows synchronisation of reproduction with seasonal cycles or act as a species isolating mechanism in closely related species. It occurs in a wide range of species including members of rodents, bears, bats, marsupials (notably kangaroos, wallabies and small possums), armadillos, seals, sea lions, skunks, mink, martins, wolverine and other mustelids, and one species of deer

Fig. 6 Relative phases of maternal investment from conception to weaning. The percentage of time spent during gestation, lactation (milk-only period) and mixed feeding (milk and solids) for elephants, macaques, pigs, rats and tammar wallabies. There are 4 classes by which eutherians are grouped based on the characteristics of the young or litter at birth. Elephants represent group 4 and are described as precocial (open eyes and haired) and nidifugous (leave the nest shortly after hatching or birth). Macaques represent group 3 and are described as precocial and transported (young are supported or carried). Pigs represent group 2 and are described as precocial and nidicolous (dependent on parent for feeding, care and protection). Rats represent group 1 and are described as altricial (closed eyes and naked) and nidicolous. Tammars and echidna are classified as altricial, nidicolous and transported. Modified from Stringer, J.M., Pask, A.J., Shaw, G., Renfree, M.B., 2014. Post-natal imprinting: Evidence from marsupials. *Heredity* 113, 145–155.

(Tyndale-Biscoe and Renfree, 1987; Renfree and Shaw, 2000, 2014; Racey and Entwistle, 2000). Diapause may be controlled by the sucking stimulus of the young during lactation, or by seasonal factors such as photoperiod, or in some cases, such as in the tammar wallaby, by both.

Parturition

The physiology of parturition is a complex process in all mammals. Successful birth ultimately depends on a precise synchronization with the appropriate maternal and fetal physiology and behaviour. Parturition is fundamental to mammalian reproduction. There are many common mechanisms but the physiology of parturition in mammals is highly diverse and almost species specific. In all species examined to date prostaglandins and oxytocin/mesotocin are critically important as regulators of uterine contractions among other roles. A broad range of other hormones are also involved, but the details of these endocrine interactions vary widely between species.

Lactation and the Mammary Gland

Lactation is the defining characteristic of mammals (Fig. 6). Presumably in the ancestral mammal secretions from cutaneous glands must have enhanced the survival of eggs or hatchlings leading to the exceedingly sophisticated mammary gland and lactation of present day mammals.

Mammary glands comprise secretory alveoli connected by milk ducts to the teat. The number, shape and size of mammary glands varies between species, and in eutherian mammals they are present in both sexes. Mammary glands never develop in Australian male marsupials, but they are present in South American marsupial males. Mammary glands develop along the “mammary line” and may be thoracic, inguinal and/or abdominal. In all female mammals with the exception of monotremes there is a nipple or teat present. In monotremes the milk ducts empty directly onto the abdominal skin in a milk patch from which the young actively suck. Male monotremes, like male eutherians, possess mammary glands.

Development of this secretory tissue depends on an array of hormones that vary between species, but prolactin, insulin, cortisol, and progesterone are notable. In mammals the mammary gland only develops in the later stages of pregnancy and undergoes rapid regression after weaning. In humans the breast, which is a prominent and permanent characteristic of the female, develops around puberty, but this comprises mostly fatty tissue rather than secretory alveoli.

In all mammals, the first milk is colostrum, a low-fat high-protein fluid with free floating cells and with abundant immunoglobulin G- and A-like proteins that provide immunological protection to the suckled young. After a few days the milk composition changes to the mature milk. Composition of the milk is highly variable between species (Table 2), but in most eutherian species, once lactation is established, there is little variation in milk composition through lactation. In marsupials and monotremes, because of the immaturity of their young, lactation lasts for relatively longer than in most eutherian species. Unlike in eutherians, where there are relatively few changes in milk composition until weaning, in monotremes and marsupials milk composition changes profoundly to match the dramatic developmental changes of the young during pouch or nest life. The changing milk composition regulates the growth and development of the young.

Release of milk from the mammary gland is regulated by oxytocin or related hormones. These act on the contractile myoepithelial cells that surround the alveoli to increase intra-mammary pressure. Sensory stimuli such as sucking induce oxytocin release from the posterior pituitary and subsequent milk ejection (letdown). Milk synthesis is controlled by prolactin from the anterior pituitary together with other hormones.

Seasonality

Most mammals breed seasonally, with mating occurring at a time of year that leads to weaning of young at the optimum time for their survival (Gilmore and Cook, 1981). Seasonality may be controlled by many factors, though photoperiod and nutritional cues

Table 2 Energy content of mammalian milk

Component	Human	Elephant seal	Tammar early	Tammar late
Water	90	35	90	85
Protein	1.1	10	4.5	10
Carbohydrate	7.5	2	5.8	2
Lipid	4.2	55	2	10
Energy (MJ/100 mL)	5.4	65.3	8.0	22.9

Fig. 7 Seasonal gonadal activity in a variety of photoperiodic mammals. Modified from Follett, B.K., 1984. The environment and reproduction. In: Austin, C.R., Short, R.V., Reproductive Fitness; Reproduction in Mammals. vol. 4, second ed., CUP.

are the most common. Photoperiod is the major environmental factor regulating seasonal reproduction (Fig. 7). When mammals are transferred from one hemisphere to the other, annual rhythms in season and photoperiod are shifted 6 months out of phase. Photoperiodic signals are mediated via circadian cycles of melatonin secretion from the pineal gland which regulates GnRH pulsatility in the hypothalamus that in turn regulates gonadotropin release from the pituitary. Similarly, nutritional or metabolic cues control seasonal cycles by modulating GnRH pulses in the hypothalamus. In species with long gestations or long lactations, the seasonal cue for onset of breeding is separated from the time of weaning by a considerable time period.

Seasonally breeding eutherian and marsupial species breed at various times of the year, depending on latitude, food availability and temperature. In some, the season lasts weeks or even months, as from early autumn to winter in the sheep, but in others, such as the tammar wallaby, the birth and mating season is highly synchronised to the photoperiod duration of the longest day. The platypus and echidna breed in the spring and wean their young 3.5–6 months later.

Conclusions

The approximately 5.5 thousand mammalian species have many reproductive features in common, but each species has its own unique reproductive pattern that adapts them to their own particular habitats and available resources. We know details about the reproduction of a mere handful of these species, yet their very survival depends on our ability to understand their needs. Comparative reproduction studies are important for this understanding.

Reproductive Organs

The eutherian ovary is located in the retroperitoneal space at the transition between abdominal and pelvic cavity. Egg cells (primary and secondary oocytes) develop in the ovary (oogenesis) and are generally yolk free. Primary oocytes derive from stem cells (primordial germ cells) and differentiate into secondary oocytes as a result of the first phase of meiotic division. Secondary oocytes remain arrested in the second phase of meiosis, which is only finished after fertilization. A fixed number of oocytes is determined around the time of birth (follicular pool). The formation of new oocytes after maturity (neo-oogenesis) is a rare phenomenon and has been reported to occur in *Mus musculus* and a number of primate species (e.g., *Galago senegalensis*, *Perodicticus potto* and *Daubentonia madagascariensis*). Follicle maturation and ovulation are regulated by hormones of the pituitary gland (hypophysis). A plasma membrane of the oocyte (oolemma) is surrounded by a Zona pellucida and a Corona radiata. Except for *Oryctolagus cuniculus*, tertiary egg membranes (muroid layer) are absent. According to the degree of paramesonephric duct fusion, the uterus can be completely paired (Uterus duplex: e.g. Lagomorpha, some Rodentia), partly fused (Uterus bipartitus: e.g. most Carnivora, some Chiroptera; Uterus bicornis: e.g. Pholidota, Eulipotyphla), or entirely fused (Uterus simplex: e.g. Primates, some Chiroptera and Xenarthra) (Fig. 1(a)). In contrast to marsupials, female eutherians are generally characterized by an unpaired vagina (monodelphy; diagnostic feature).

Testicles descend outside the abdominal cavity (Descensus testiculorum) and can be located either scrotal (e.g. Primates, Artiodactyla, Perissodactyla), or inguinal (e.g. Cetacea, Eulipotyphla, Pholidota). True testicondy (testicles not descended) occurs in Afrotheria and Xenarthra. In contrast to marsupials, eutherian males are characterized by a postpenial position of the scrotum (if present). In eutherians a variety of male accessory sex glands are present, which are important for the activation and transport of spermatozoa and other reproductive parameters (e.g., formation of a vaginal plug in some rodents and carnivores).

Sexual Cycle

After reaching puberty, females of most eutherian species possess an estrus cycle in terms of periodic physiologic changes of reproductive organs (and sexual receptivity) according to distinct phases: proestrus, estrus, metestrus, and anestrus. Sexual activity of females is strictly limited to a defined phase of sexual receptiveness (estrus phase), also as an adaptation to seasonal conditions. Seasonality of reproduction can also vary according to specific ecological conditions, even within one species. Depending on the cycle frequency, taxa can be grouped into monoestrous, diestrous, and polyestrous. In nonconceptive cycles, the endometrium is reabsorbed down to a basic layer. Domestication can lead to an increase in the cycle frequency and hyper-sexuality.

Within different groups of primates (Pongidae, Hominidae and Callitrichidae), an ovarian cycle, or a menstrual cycle, has evolved. In taxa with a true menstrual cycle, the endometrium regularly undergoes dissolution through menstruation (tissue shedding and bleeding), if conception does not occur.

Most eutherians ovulate periodically during a specific season (estrus). However, in several species and among various systematic groups, ovulation is triggered by external stimuli (induced ovulation; Carnivora, Lagomorpha, Rodentia, Eulipotyphla, Artiodactyla, Perissodactyla and Scandentia). In primates (and possibly other taxa), ovulation occurs spontaneously without mating-induced stimuli.

Females of some eutherian species communicate their reproductive status via scent glands and scents may even modulate reproductive physiology. Some callitrichids (Primates), for example, use olfactory clues (scents) to transmit information on reproductive status (e.g. identification of fertile phase of the ovarian cycle) and social status in order to adopt strategies depending on their socio-sexual role in the group (group cohesion). Other signals (e.g., visual, acoustic, and behavioral) are also important for the reproduction of eutherians.

Fertilization

In most eutherians, fertilization occurs in the uterine tubes (Tuba uterina). In some Eulipotyphla (Tenrecidae and the shrew *Blarina brevicauda*), the oocyte is fertilized in the ovary. Polyembryony, the development of a single fertilized oocyte into two or more genetically identical embryos, can occur in various eutherian taxa (including humans). Polyembryony is common in Dasypodidae; between two and 12 embryos develop from one fertilized oocyte. With the exception of some Macroscelididae, the number of ovulated oocytes resembles the number of offspring delivered.

Oviduct Oocyte Transport

In contrast to monotremes and marsupials, cleavage in eutherians is equal and holoblastic. Coordinated oviduct musculature contractions, tubal fluids, and ciliary movement of the epithelium transport the cleaving oocyte through the uterine tube towards the uterus (**Fig. 1(b)**). A glycoprotein layer (Zona pellucida) prevents the fertilized oocyte (zygote) from implantation into the tubal epithelium. In eutherian taxa studied, the period of oviduct zygote transport varies between 2 days (*Sus scrofa* f. domestica) and 6 days (*Neovison vison*, *Equus przewalskii* f. caballus) but can be greatly prolonged in bat species possessing delayed fertilization.

Blastocyst

The eutherian blastocyst is characterized by an early differentiation into two distinct cell types: an outer layer of epithelial trophoblast cells and an aggregated inner cell layer (embryoblast) (**Fig. 1(c)**). The displacement of the embryoblast inside the germinal vesicle (trophoblast) is an apomorphic character of eutherians (entypy of the embryo). At an early stage, the blastocyst is surrounded by a glycoprotein layer (Zona pellucida). The embryoblast differentiates into two epithelial layers: epiblast (adjacent to the uterine wall) and hypoblast (adjacent to the blastocyst cavity).

Once arrived in the uterus, the Zona pellucida dissolves and releases the trophoblast. Mononuclear trophoblast cells begin to proliferate and differentiate into a multinuclear cell mass developing into a syncytiotrophoblast (outer layer) and a cytotrophoblast (inner layer). The cytotrophoblast produces lytic enzymes dissolving the extracellular matrix and allowing the active invasion of the syncytiotrophoblast into the endometrium. The syncytiotrophoblast forms the developing interface between fetus and maternal tissues or blood. A syncytiotrophoblast can also occur in marsupials, where it is regulated by retroviral genes, which have also been found in eutherians. Functionally, the syncytiotrophoblast seems more related to fetomaternal metabolism than immunotolerance. The syncytiotrophoblast evolved independently in marsupials and eutherians and even within eutherians (convergent evolution).

The invading (anti-genetically foreign) trophoblast is tolerated in the uterus; a phenomenon referred to as “immunological paradox of pregnancy”. The trophoblast escapes allorecognition and is protected from maternal immune system mediated by different immunotolerogenic mechanisms. A layer of fibrinoid can further protect the blastocyst.

Implantation

Fetal and maternal tissues are initially brought into close contact via trophoblast-uterine epithelial interactions. Implantation requires a state of “receptivity” of the endometrium (implantation window) and, in accordance with the degree of invasiveness of placentation, a certain degree of invasiveness of the trophoblast. Based on the degree of trophoblast-uterine epithelial interactions, different types of implantation can be distinguished (superficial vs. invasive). The least degree of invasiveness can be found among many Artiodactyla, Carnivora and Lagomorpha. Here, the blastocyst is located in the center of the uterine cavity (central implantation). In eutherian species with invasive implantations, the trophoblast uses different modes of penetrating the uterine epithelium. In species with hemochorial placentation, the fetal trophoblast invades maternal vasculature to form an intervillous space through which maternal nutrients pass to the growing fetus. Shortly after the initial invasion of the trophoblast, fetal blood vessels form fetal villi that are in direct contact with the maternal circulation.

In contrast to marsupials and as a consequence of a lack of an immune-protective shell coat, eutherians are characterized by a complex cascade of immunological pathways (antigen expression, regulated apoptosis, production of anti-inflammatory cytokines) leading to the immune-tolerance of the allogenic embryo by the maternal system during pregnancy.

Placentation

Eutherians are characterized by a chorioallantoic placenta, which forms the main organ of fetomaternal exchange. Chorioallantoic tissue (chorionic folds or villi) can deeply invade the maternal endometrium. An additional yolk sac placenta, which can be found in many eutherians at an early stage of gestation, loses its function (e.g., supply of iron-rich histotrophe to the embryo), when the definite chorioallantoic placenta has fully developed and provides iron supply, e.g. via hemophagous regions. Among eutherians, a vast variety of chorioallantoic “placental types” can be found. Various classifications schemes are in use, each focusing on different aspects of the complex continuum of eutherian placentation. It is, however, important to note that these schemes lead to artificial categories, which do not resemble phylogenetic associations among eutherians.

One classification approach refers to the placental shape and the degree of placental tissue concentration: In diffuse placentas (Placenta diffusa), the chorionic villi are distributed over the entire inner surface of the gestation chamber (Perissodactyla, Strepsirhini, Suidae). Cotyledone placentas (Placenta cotyledonaria) are characterized by small areas of placental tissue concentration in the form of so-called cotyledons or placentomes (most Artiodactyla). Zonary placentas (Placenta zonaria) show a restriction of chorionic villi to a circular zone (Carnivora, many Afrotheria). In discoidal placentas (Placenta discoidalis), the syncytium of chorionic villi forms a discoid area (Rodentia, most Primates, Afrosoricida, Chiroptera, Eulipotyphla).

Another widely used criterion to classify the different “placental types” refers to the composition of the interhemal barrier. According to the degree of placenta invasiveness and erosion of maternal tissue (superficial vs. invasive), the following “placental types” can be distinguished (**Fig. 1(d)**, **Table 1**):

- Epitheliochorial: chorionic villi attach to the intact uterine epithelium, the trophoblast does not erode the uterine epithelium (Cetacea, Perissodactyla, Lemniformes).

Table 1 Summary of data on reproduction and development for eutherian species—cont'd

Order Species	Placentation (interhemal barrier)	Pregnancy (days)	Lactation (days)	Mammilla (location)	Litter size	Eye opening (days)	Furring (days)
<i>Pipistrellus pipistrellus</i>	hc	44	60	2 (p)	2	5	7–14
<i>Rousettus leschenaulti</i>	enc	125	60	2 (p)	1	0	0

Abbreviations: hc, hemochorial; sc, syndesmochorial; enc-endotheliochorial; epc, epitheliochorial; p, pectoral; a, abdominal; i, inguinal; na, not available. Summarized info based on the following references: Roberts, R.M., Green, J.A., Schulze, L.C., 2016. The evolution of the placenta. *Reproduction* 152 (5), 179–189; Mess, A.M., Ferner, K., 2010. Evolution and development of gas exchange structures in Mammalia: The placenta and the lung. *Respiratory Physiology & Neurobiology* 173 (S), S74–S82; Ferner, K., Siniza, S., Zeller, U., 2014. The placentation of eulipotyphla – reconstructing a morphotype of the mammalian placenta. *Journal of Morphology* 275 (10), 1122–1144.

- Syndesmochorial: the trophoblast partly erodes the uterine epithelium, chorionic villi attach to the underlying tissue (most Artiodactyla).
- Endotheliochorial: the trophoblast erodes the uterine epithelium and underlying tissue and may directly attach to the maternal capillary endothelium (Carnivora, some Chiroptera and Eulipotyphla).
- Hemochorial: the trophoblast erodes all maternal tissue layers (including maternal capillary endothelium) and gets direct access to the maternal blood (Haplorhini, most Lipotyphla, some Chiroptera and Rodentia).
- Hemoendothelial: chorionic villi erode, the endothelium of the chorionic capillaries comes into direct contact with the maternal blood (*Oryctolagus cuniculus*, some Rodentia).

A different classification scheme refers to the placental fate at birth: in non-deciduous placentas (epitheliochorial type), chorionic villi easily detach from maternal tissue without causing maternal tissue damage during parturition. In deciduous placentas (all other placentas), a variable amount of maternal tissue is expelled at birth.

In contrast to the hypothesis, whereas superficial placentation modes represent a rather ancestral (plesiomorphic) state, recent findings on the placentation modes within Eulipotyphla lead to the assumption that invasive and compact placentation and the occurrence of altricial neonates represent the eutherian neonate morphotype.

Parturition

The parturition process underlies a complex interplay between fetal and maternal factors. Parturition is triggered by multiple fetal-maternal control mechanisms. With the onset of labour, the myometrium transforms from a quiescent state (important for fetal development during gestation) into a coordinately contracting organ; uterine contractions increase in frequency, intensity and duration. This transformation of the state of uterine musculature is associated with the dilatation of the uterine cervix in order to allow the passage of the fetus from the uterus. A variety of hormones of different origin is involved in the complex pathway of uterine contractility and parturition, including corticotropin releasing hormone, estrogens, progesterone, prostaglandins, oxytocin, and relaxin. The rearrangement of the extracellular matrix of the cervix (cervical ripening) is triggered by prostaglandines, relaxin, and inflammatory cell products. Progesterone plays a crucial role in the control of labour.

Neonates

In general, the length of the gestation period in eutherians is positively correlated with body weight and the degree of development of the newborn. As a general rule, the larger the species, the longer the gestation period (for mammals of equal weight, the species with the heaviest neonate has the longest gestation).

Eutherian mammals give birth to neonates of varying developmental degrees; generally categorized under the terms altricial and precocial (Fig. 1(e)). However, a wide spectrum of developmental degrees of neonates can be found along this spectrum. In contrast to marsupials, no permanent fixation to the nipples exists. However, in some desert rodents (*Baiomys spec.* and *Neotoma spec.*), a temporary fixation was described. Different aspects of development are discussed to define altriciality and precociality in eutherians: brain development, transitory closures, thermoregulatory, sensory, locomotory, and nutritional development.

Altricial neonates (Eulipotyphla, many Rodentia, some Chiroptera, Scandentia, many Carnivora, *Oryctolagus cuniculus*) are characterized by (1) closed eyes and ears, (2) hairless or sparsely haired, nearly translucent skin, (3) poor thermoregulation, (4) incomplete jaw development, (5) postnatal brain maturation, and (6) limited locomotion (neonates usually remain in a nest site).

Precocial neonates (Cetacea, Sirenia, Proboscidea, Hyracoidea, Perissodactyla, Artiodactyla, some Chiroptera, Macroscelidea, some Carnivora [Odobenidae, Phocidae, Otariidae], Rodentia [Hystricognathi], *Lepus europaeus*) are characterized by (1) open eyes and ears, (2) being completely furred (except Cetacea), (3) functioning thermoregulation, (4) complete jaw development, (5) prenatal brain maturation, (6) coordinated locomotion (no nest site). Precociality evolved on many occasions independently during eutherian evolution and can be found among almost all eutherian taxa.

Lactation

Lactation and parental care are fundamental adaptations concerning the reproduction of mammals. Lactation (and consequently the ability to suck) is a shared, derived (synapomorphic) character of mammals. In fact, the term Mammalia derives from the

mammary glands. These glands in females provide nourishment for the young during their postnatal period of rapid growth. Located along the paired mammary line, mammary glands are monoptyche (unilaminar layer of secreting cells), tubular, cutaneous glands with apocrine and eccrine secretion. They consist of a complex system of ducts that reach the surface of the skin through the mamilla. During late pregnancy, the growth and preparation of the mammary glands is stimulated by endocrine secretions (estrogens, progesterone, insulin, lactogen, and growth hormones). The epithelium of the ducts divides rapidly to produce secretory alveoli, which produce milk after birth. From the spacious alveoli (mammary gland), the milk passes via Ductus lactiferi into the cistern (Sinus lactiferous) and flows finally via milk ducts (Ductus papillares) into the mamilla (Fig. 6(f)). The production of milk is regulated by secretions from the pituitary (prolactin, oxytocin, and growth hormones). The milk flow is stimulated by nursing and emptying of milk from the mammary glands and continues until the stimulus ceases. The percentage composition of milk differs between eutherian species; however, the main components of the milk are the same (water, casein, whey proteins, carbohydrates, milk fat globules, and minerals). A major change in eutherian milk composition occurs after the first few days of lactation, during which colostrum (diluted liquid containing high levels of antibodies) is produced, followed by copious milk secretion of relatively constant composition.

The number and position of the mamillae is variable among eutherians and varies between 2 (e.g. most Primates, Proboscidea, Perissodactyla) and 24 (*Tenrec ecaudatus*, *Mastomys natalensis*) (Table 1). The location of the mammary glands corresponds to the paired mammary line; however, the exact position on the longitudinal axis is variable. Following positions can be distinguished:

- thoracic: Proboscidea, Sirenia, Chiroptera, Primates
- abdominal: Eulipotyphla, Rodentia, Carnivora, Suidae
- inguinal: many Artiodactyla, Cetacea, Perissodactyla

In contrast to marsupials, where the lactation period is always longer than gestation, the lactation period of eutherians can be shorter or longer than gestation. A high variability with regard to the duration of lactation exists among eutherians from about 7 days (or even less) in elephant shrews to 730 days in elephants (Table 1).

Ecology

In general, the eutherian embryonic and fetal development (the development between fertilization and parturition) is a continuous process. However, eutherians exhibit a pronounced plasticity in reproductive strategies towards ecological conditions. These adaptations refer to different stages of fetal and early postnatal development.

Delayed fertilization (delay of ovulation and fertilization until weeks or even months after copulation) is an adaptation towards periods of limited seasonal resource availability. It occurs in several species of mostly insectivorous and hibernating Chiroptera distributed over temperate ecosystems in the Palearctic and Nearctic region. In these species, copulation and insemination takes place before or during hibernation. The sperm is stored in the uterus or vagina for periods up to several months after copulation. During this time, secrets of the uterus keep the sperm viable. Directly after emergence from hibernation, ovulation, fertilization and implantation takes place in order to initiate gestation (and consequently parturition) at the earliest possible time of the respective season.

Phases of delayed embryonic development do also occur at the blastocyst stage (delayed implantation). While fertilization and early cleavage occur as usual, implantation does not take place immediately after the fertilized oocyte (blastocyst) reaches the uterus. Instead, the blastocyst maintains a state of minimal development and cleavage (dormancy) and remains free in the lumen of the uterus, without attachment to the uterine wall. Delayed implantation evolved independently in many occasions and occurs in various eutherian taxa. It can be found in Eulipotyphla (*Sorex araneus*, *Talpa altaica*), Chiroptera (e.g. *Lasionycteris noctivagans*, *Miniopterus schreibersii*, *Rhinolophus rouxii*), Xenarthra (*Dasyus hybridus*, *Dasyus novemcinctus*), Carnivora (Ursidae, Mustelidae, Mephitidae, Odobenidae, Phocidae, Otariidae), and Artiodactyla (*Capreolus capreolus*). The length of the delay is highly variable and can range from 30 days (*Neovison vison*) to 10.5 months (*Martes pennanti*).

In some taxa, delayed implantation only occurs under certain environmental conditions, including food deprivation and concurrent lactation (facultative diapause). Facultative diapauses can be observed in a number of species that show an estrus immediately after parturition (postpartum estrus). In these species, the delay is triggered by the suckling stimulus of the current litter in order to avoid the “double burden” of undergoing the stages of gestation and lactation at the same time. Other taxa exhibit an obligate diapause. In these taxa, delayed implantation is a regular part of the reproductive cycle, enabling an optimal timing of the birth of neonates in view of seasonal resource availability (seasonal embryonic diapause).

A less common type of reproductive delay refers to a period of slow or suppressed development of the embryo after implantation but prior to birth (delayed development). Delayed development has been found in a small number of bat species (*Macrotus californicus*, *Artibeus jamaicensis*, *Otopteropus cartilagonodus*, *Haplonycteris fischeri*, *Ptenochirus jagori*). In order to reduce metabolic demands of the embryo, delayed development occurs early after implantation. It enables a high degree of flexibility towards unfavorable environmental conditions and the synchronization of the timing of parturition in “nursery colonies”.

Another adaptation of reproductive strategies is the “pregnancy blocking phenomenon” or “Bruce-effect” observed under laboratory or captive conditions in a number of rodent species (e.g. *Mus musculus*, *Microtus pennsylvanicus*, *Microtus ochrogaster*, *Peromyscus maniculatus*), as well as in the domestic horse (*Equus przewalskii* f. *caballus*). In recently pregnant females, the exposure of the scent of an unfamiliar male can trigger pregnancy disruption during an early developmental stage of the embryo (before implantation). Direct evidence for the occurrence of a “Bruce-effect” under natural conditions is lacking and there is a debate,

whether this phenomenon might be an artefact. Recent data on observed pregnancy terminations and inter-birth intervals in free-ranging geladas (*Theropithecus gelada*) reveal arguments for the existence of pregnancy blocking strategies in primates under natural conditions. An early termination of pregnancy is also discussed as an adaptation strategy to avoid nonparental infanticide (see below).

Several eutherian taxa are known to directly affect the reproductive performance of conspecifics by committing nonparental infanticide. The killing of immature offspring by nonparental conspecifics (males and, or females) occurs in a wide variety of eutherian taxa (Primates, Carnivora, Rodentia, Artiodactyla, Perissodactyla, Lagomorpha, Chiroptera and Scandentia). Several theories exist to explain this behavior, including nutritional and resource-competitive aspects. Nonparental infanticide committed by males is also interpreted as a strategy to increase access over breeding females and optimize reproductive success.

In summary, eutherian mammals are characterized by a pronounced plasticity of reproductive strategies, enabling niche realization in virtually all existing habitats (aquatic, terrestrial, and aerial). Owing to the resulting ecological flexibility, eutherian mammals represent approximately 96% of all extant mammalian species.

Glossary

Alternation of Generations A life cycle with alternating multicellular diploid and multicellular haploid stages.

Angiosperm The flowering plants, which comprise the majority of living plant species.

Dioecious Bearing male and female reproductive structures on separate individuals.

Diploid A cell with two compliments (copies) of chromosomes.

Gamete The male or female single celled haploid (1 n) units of sexual reproduction.

Gametophyte The multicellular, haploid (n) phase of the alternation of generations, which produces male and/or female gametes by mitosis.

Haploid A cell having only one compliment of chromosomes.

Heterosporous Producing two different sized spores, the smaller of which produce male gametophytes, the larger produce female gametophytes.

Homosporous Production of only one size of spore that may develop into a male, female, or bisexual gametophyte.

Monoecious Bearing male and female reproductive structures on the same individual.

Seed A diploid plant embryo encased in a protective coat.

Sporangium A receptacle in which asexual spores are formed.

Spore The single celled haploid product of meiosis by a sporophyte.

Sporophyll A leaf that bears sporangia.

Sporophyte The multicellular diploid (2 n) stage of the alternation of generations which produces spores by meiosis.

Strobili A collection of sporophylls that form a cone like shape.

Introduction

Kingdom Plantae is broadly composed of four evolutionarily related groups: bryophytes (mosses), (seedless vascular plants), gymnosperms (cone bearing seed plants), and angiosperms (flowering seed plants). These groups share features such as the production of embryos, photosynthetic chloroplasts, and cell walls primarily composed of cellulose. A variety of reproductive strategies can be found in plants, both sexual and asexual, often with more than one strategy utilized by a single species. While the aforementioned groups are primarily divided by differences in reproductive strategy, all land plants share a reproductive phenomenon named the *Alternation of Generations* (Fig. 1). This is characterized by a reproductive cycle that has both a multicellular *diploid* (2 n) as well as a multicellular *haploid* (1 n) stage. In this cycle the *sporophyte* (multicellular diploid) undergoes meiosis to produce haploid cells called *spores*. These spores then divide by mitosis to form the multicellular haploid *gametophyte*, which will in turn produce the male and female *gametes*. Unlike in animals, gametes are produced by mitosis in plants since the gametophyte is already haploid. These gametes fuse to produce a diploid *zygote*, which will then undergo mitotic divisions leading back to the sporophyte stage.

The ancestors of land plants were aquatic green algae and the transition to life in terrestrial environments presented a number of challenges not least in regard to reproduction. Indeed novel reproductive structures that enhance desiccation tolerance and remove the need for water in gamete transfer are predominant characteristics in the classification of these organisms. In addition, throughout the evolution of land plants the haploid gametophyte stage of the life cycle has been progressively reduced, from being the dominant life stage in bryophytes, to only 3–9 cells in *angiosperms* (flowering plants). This trend towards dominance of the diploid sporophyte and reduction of the haploid gametophyte life stages is often interpreted as being an adaptation to the substantially higher levels of mutagenic UV light in terrestrial than aquatic environments, favoring diploids which inherently possess a “back-up” set of genetic material.

Evolution of Land Plant Reproduction Overview

Estimates put evolution of the earliest land plants between 500 and 450 million years ago (MYA). As stated above, all land plants display Alternation of Generations, but the details by which they carry out this life cycle have changed drastically through evolutionary time. The earliest land plant fossils originated around 430 MYA and bear a strong similarity to the extant group of plants known as the Bryophytes, which includes liverworts, hornworts and mosses. In Bryophytes, the gametophyte (1 n) stage is the dominant life stage making up the bulk of the biomass. The gametophyte generates male and female reproductive structures known as antheridia and archegonia, respectively. Antheridia in these groups produce flagellated sperm cells that require water to swim to the archegonia and fuse with the egg cell contained within. The resulting embryo and sporophyte (2 n) is nutritionally dependent on the mother gametophyte and will grow out of the top of it. Ultimately, the sporophyte forms a single *sporangium*

Fig. 1 The alternation of generations life cycle in land plants involves both a multicellular diploid ($2n$) stage, the sporophyte, and a multicellular haploid ($1n$) stage, the gametophyte. Unlike animals, meiosis in plants does not produce gametes but instead the sporophyte produces haploid single celled spores. A spore divides by mitosis to form a multicellular ($1n$) gametophyte. The gametophyte produces ($1n$) gametes by mitotic division. Fusion of the gametes yields a ($2n$) zygote, which will develop into a new sporophyte.

where $1n$ spores are produced by meiosis. These spores are the main dispersal structure of the bryophytes, and are primarily wind born. A thick wall of sporopollenin protects the spores from degradation and desiccation until ideal growth conditions are encountered.

The evolution of water and nutrient conducting vascular tissues, around 400 MYA, allowed plants to develop larger branched, body structures which had significant impacts on reproductive strategies. The first plants to utilize this are referred to as the seedless vascular plants. Though species diversity in this group was once extensive there are only two extant phyla, the Lycopodiophyta (club and spike mosses, and quillworts) and the Monilophyta (ferns and horsetails). Seedless vascular plants differ from bryophytes in that the sporophyte is the larger dominant stage of the life cycle, and is free-living and independent of the gametophyte at maturity. Spores are still the main dispersal structure, but the branching nature of the sporophyte allows more than one sporangium on an individual and hence greater spore production. In some species spore production occurs in specialized structures called *strobili* (cones), which form at the tips of branches. In ferns, however, sporangia are borne in large numbers on leaves known as *sporophylls*. While the majority of seedless vascular plants are *homosporous*, making only one type of spore, which develops into a gametophyte that can produce both antheridia and archegonia, many lycophytes and some ferns are *heterosporous*. In heterosporous plants two different types of spore are produced, *megaspores*, which develop into female gametophytes, and *microspores*, which become male gametophytes. These unisexual gametophytes are often highly reduced in size and complexity compared to the bisexual gametophytes of homosporous species. Heterospory is the norm in later plant groups and appears to have had multiple evolutionary origins in the vascular plants.

Evolution of the next key reproductive structure, the *seed*, provides the name of the next group, the gymnosperms (which translates to “naked seed”). A seed consists of a fertilized embryo packaged with stored food and encased in a protective seed coat. The seed represents a change in dispersal strategy, with spores no longer being the dispersal structure, and a dramatic shift in the alternation of generations life cycle. The gametophytes are highly reduced in size, with the female gametophyte no longer being free-living, instead being retained within the parental sporophytes megasporangium. Additionally, transfer of the sperm to the egg is no longer reliant on water. The male gametophytes (microgametophytes) develop into pollen grains, which facilitate transfer of sperm to the megagametophyte by alternative means, generally wind. As a consequence of the inefficiency of wind pollination, there is a shift to producing very large quantities of male gametophytes (pollen), which you may have observed as large clouds wafting off conifer trees. The gymnosperms consist of four extant phyla: Coniferophyta (conifers), Cycadophyta (cycads), Ginkgophyta (ginkgo), and Gnetophyta (gnetophytes). While the earliest seed-like structures found in the fossil record are found around 365 MYA, the origins of extant gymnosperms are more likely around 290 MYA.

The majority of extant plant species (> 300,000) are contained within the Angiosperms (flowering plants). The angiosperms are characterized by the evolution of key reproductive structures, flowers and *fruits*. The first angiosperm fossils date from around 130 MYA and they quite rapidly became the dominant plant group by 90 MYA. As can be observed in any florist shop, the flower has evolved a staggeringly diverse range of forms, shapes, colors, sizes, etc. This great diversity is directly related to the flower's role in enhancing the efficiency of pollination, frequently through relationships with animal pollinators, which often replace wind as pollen vectors. This structure is one of the primary reasons the angiosperms were able to dominate plant biodiversity in such a

Fig. 2 A phylogenetic tree of land plant lineages. Key evolutionary traits are indicated by red lines, and are shared by all groups above their appearance. This figure is not to scale with evolutionary time.

short (geologically speaking) period of time. The evolution of fruit, which are formed from ovary tissue after fertilization, both protects the seeds as well as promoting dispersal by various biotic and abiotic means. Following the trend seen in the other groups, the gametophytes are even further reduced in the angiosperms, with the pollen containing only 3 nuclei and the female gametophyte (embryo sac) containing 7–9 nuclei. The fertilization process is also modified in the flowering plants and involves both sperm cells found within a pollen grain. One fuses with the egg cell to produce the zygote, the second fuses with the two haploid polar nuclei in the embryo sac forming the triploid (3 n) *endosperm*. This tissue is highly nutritive, aiding the developing zygote. This process is known as *double fertilization* (Fig. 2).

Details of Reproduction in Non-Seed Plants

Bryophytes

Sexual reproduction

The gametophyte is the dominant life phase in the Bryophytes. The gametophyte produces structures known as antheridia and archegonia, which produce the male and female gametes respectively. Collectively these structures are known as *gametangia*. While some bryophyte species have gametophytes that produce gametangia of both sexes on a single individual, others have separate male and female gametophytes. The antheridia produce many biflagellate sperm cells, which require liquid water to swim to the egg cell. Archegonia in contrast produce a single egg cell located within a chamber known as the *venter*. A canal to the outside forms within the neck of the venter and breakdown products of cells that degenerate to form this canal generate a signal that serves as a chemoattractant to the sperm cells. When a sperm cell swims down to the egg cell they fuse to form the diploid (2 n) zygote. This embryonic sporophyte will continue to develop in the archegonium and will continue to remain attached to, and nutritionally dependent on the parental gametophyte for the entirety of its life. For mosses the gametangia are often positioned at the top of the “leafy” gametophyte axis. The zygote and resulting sporophyte will develop and grow out of the archegonia on top of the gametophyte. When mature, a spore generating structure (sporangium), called a capsule, forms at the top of the sporophyte. Spores (1 n) are generated by meiosis and as the capsule matures it dries and finally pops open releasing the spores for dispersal. Given appropriate conditions, these spores will develop into new gametophytes. Positioning of gametangia and the resulting sporophytes differs in the different bryophyte lineages. The common liverwort *Marchantia* produces umbrella shaped structures that raise the gametangia above the main gametophyte body and the sporophytes develop on the underside of these structures. In the hornworts, the sporophyte structures provide the common name for this group as they rise out of the thalloid gametophyte like horns. The sporangia grow upward out of the apex of this sporophyte.

Asexual reproduction

Bryophytes often divide vegetatively with one individual breaking into several pieces that can become free-living individuals. Additionally, many bryophytes gametophytes produce structures known as *gemmae*, which are small balls of cells contained in cuplike structures known as splash cups. Falling water can splash gemmae out of the cups and when they reach soil they will divide to form a new gametophytes.

Seedless Vascular Plants

Sexual reproduction

This group was highly species rich and diverse from around 400–300 MYA, but many of those diverse lineages have gone extinct leaving a somewhat fragmented patchwork of reproductive mechanisms in the group when observed as a whole. The seedless vascular plants all exhibit a shift in the alternation of generations to a larger free-living sporophyte (2 n), and a general reduction

in size of the gametophyte ($1n$). The sperm produced are still flagellated and require water to swim to the egg in the archegonia. An important development that independently evolved several times in this group is heterospory. This is characterized by the production of two different types of spores, microspores that develop into unisexual male gametophytes, and megaspores which become unisexual female gametophytes. While unisexual gametophytes are found in many homosporous species there is no observable difference in the spores they arise from. In the living Lycopodiophyta species: spike mosses (Selaginellaceae) and quillworts (Isoetaceae) are heterosporous, while club mosses (Lycopodiaceae) are homosporous. Many club moss and spike moss species produce spores in specialized structures called strobili, which are a group of modified non-photosynthetic sporophylls (spore bearing leaves). The largest number of seedless vascular plant species is in phylum Monilophyta and the majority of these are ferns. Almost all are homosporous, with the water ferns being the only living heterosporous ferns. Fern sporangia are grouped into structures called *sori*, which are generally dot shaped in appearance, and are most often found on the underside or around the edges of leaves. Fern gametophytes are often small and heart shaped, and some bisexual gametophytes develop antheridia and archegonia at different times to increase the probability of cross-fertilization. After fertilization, the emerging sporophyte grows out of the gametophyte and obtains nutrients from it until the former is large enough for nutritional independence, at which point the gametophyte degrades. One familiar group of non-fern Monilophytes is the horsetails (*Equisetum*), which produce a sporophyte with a green photosynthetic stem with a large distinctive strobilus at the top of this axis. The homosporous spores from this can give rise to gametophytes that are either bisexual or exclusively male to promote cross-fertilization.

Asexual reproduction

There are very few seedless vascular plants with specialized asexual reproduction mechanisms. Due to the rhizomatous structures of many of the seedless vascular plants such as the lycophytes and *Equisetum*, roots form along the length of the rhizome and if the rhizome is split these continue to grow as separate individuals. There are also several fern species that grow exclusively as gametophytes, reproducing only asexually and never developing sporophytes.

Details of Reproduction in Seed Plants

Gymnosperms

Sexual reproduction

The gymnosperms present another shift of the alternation of generations, with a further major reduction in the size and complexity of the gametophyte ($1n$) as well as the use of seeds as the primary dispersal agents rather than spores. As the majority of extant gymnosperm species are conifers we will focus on sexual reproduction in this group (using pines as a common example) and later highlight significant differences in non-conifer gymnosperms. Conifer sporophytes are large, woody, shrubs or trees, which are heterosporous, producing megaspores and microspores in separate cones (strobili). In *monoecious* species, female and male cones are both present on a single individual, while in *dioecious* species female and male cones occur on different individuals (Williams, 2009).

Within the male cones the many microsporocytes undergo meiosis, each producing four microspores per meiotic event. These microspores then divide by mitosis each forming a male microgametophyte (*pollen grain*). In gymnosperms (and the later angiosperm lineage) the microgametophyte is reduced to a structure containing just a few cells. Pollination, the transfer of pollen to the megagametophyte, in gymnosperms is carried out by the wind and the pollen grains possess two air sacs to aid this process. Hence pollen provided a novel mechanism for transfer of the sperm to the egg cell, with free liquid water no longer being necessary. The gymnosperm pollen grain consists of four cells, the tube cell, the generative cell, and two prothallial cells. This microgametophyte is not fully mature and only becomes so after it has been transferred to the megagametophyte.

The female (ovulate) cones bear structures called ovuliferous scales, which each produce two ovules. The ovule, which after fertilization will become the seed, is initially made up only of parental sporophyte tissue, and consists of a tissue called the nucellus, surrounded by a layer called the integument that has an opening named the micropyle through which a pollen tube will enter. The ovule will only begin development of the female gametophyte (megagametophyte) after pollination has occurred. When the pollen grain has been transferred to the receptive ovule it germinates to form a pollen tube and the generative cell divides to form stalk and body cells, the latter will produce the sperm cells. The time between pollination and pollen germination varies between different conifer genera from almost immediately to several months after pollination. Once the pollen tube begins moving through the nuclear tissue it will stop and appear dormant for a period of time.

Only after this initial pollen germination has occurred will the female gametophyte begin to develop, although this can be delayed by several months. The megaspore mother cell divides by meiosis forming four megaspores, only one of which will survive and divide to form the megagametophyte. The female gametophyte is not free-living and is contained within the ovule, dependent on the parental sporophyte for nutrition. As the pollen tube makes its way toward the developing female gametophyte the body cell divides forming two sperm cells (male gametes). The megagametophyte forms several archegonia, which each produce egg cells (female gametes). Once a pollen tube reaches an archegonium the two sperm cells are released, but only one fuses with the egg cell. The time it takes for this reproductive process to reach completion varies, and in some species spans multiple years. After fertilization, the ovule develops into a seed, which consists of tissues from three generations, the parental sporophyte, the female gametophyte, and the new zygotic sporophyte. Unlike in previous plant lineages the seed is the dispersal structure. In some

conifers, such as yews and junipers the seed develops a fleshy seed coat called an *aril* (often called a berry, although it is not truly a fruit as it is formed from the integument of the ovule rather than ovary tissues). Gnetophytes like conifers have non-motile sperm, but cycads and *Ginkgo* still produce flagellated sperm, which are released by the pollen tube in the nucellus and swim to the archegonia in a pollination drop secreted by the ovule. Interestingly, many cycads are insect pollinated, representing the first instances of the use of animal pollinators in the evolutionary history of plants.

Asexual reproduction

Specialized asexual reproduction appears to be rare in gymnosperms. In the conifers, which are some of the best-studied gymnosperms due to their economic importance, some species can be propagated from cuttings, although there is little evidence to suggest that this occurs without human intervention. There is also at least one reported case of apomixis (formation of seeds asexually). Asexual reproduction in *Ginkgo*, cycads, and gnetophytes is possible but again does not appear to be common without human intervention.

Angiosperms

Sexual reproduction

The name Angiosperm translates to “vessel seed” which refers to ovules being enclosed in the female gynoecium (*carpel*). The carpel is one of the organs that make up what is arguably the defining feature of the angiosperms, the flower. Flowers are produced by Angiosperm sporophytes and composed of four types of organs arranged in whorls: sepals, petals, stamens and carpels (see Vol. 6 #22). In most angiosperms flowers are hermaphroditic, containing both male and female reproductive parts, but monoecious species with unisexual flowers are found, as well as dioecious species. Pollen is produced in the anthers of the stamen, while the ovules are produced in the ovary of the carpel. Microsporogenesis in the anther involves the meiotic division of pollen mother cells, which each produce four microspores. These then undergo mitosis to form pollen grains (microgametophytes), which at maturity consist of only three cells, the tube cell and two non-motile sperm cells. Each pollen grain is encased in a thick protective sporopollenin wall and dries to a desiccated state for dispersal. In many species the microgametophyte is “mature” only after pollen germination, as the pollen grains possess a single generative cell, which divides only after pollination and subsequent germination to form two sperm cells. On the female side, development of the megagametophyte proceeds slightly differently in various angiosperm lineages. Here we discuss the most common mechanism. In the ovary ovules are attached to an internal wall by placenta tissue. The megasporocyte within the ovule nucellus divides by meiosis forming four haploid cells, only one of which will survive. The nucleus of this megaspore divides mitotically to form the female gametophyte, the embryo sac, which has a total of eight nuclei that will form seven cells. Six of these, including the egg cell are haploid (1 n), while critically one cell (the central cell) contains the remaining two polar nuclei. While not truly diploid (2 n) this cell is critical in the development of the seed.

Pollination occurs when pollen is transferred to a receptive surface, known as the *stigma*, of the carpel. This pollen will then germinate and produce a pollen tube that grows down the style, which connects the stigma to the ovary, to the ovule(s). Pollen tubes follow chemical signals released by two cells located at the tip of the embryo sac known as *synergids*. When a pollen tube reaches a synergid cell, the tip bursts releasing the two sperm cells into the synergid. One of the sperm will then fuse with the egg cell to form the diploid (2 n) zygote, while the other will fuse with the two nuclei contained in the central cell to form a triploid (3 n) tissue called the endosperm. This process is known as double fertilization, and is unique to angiosperms. The endosperm tissue is important for two reasons. First this tissue contains large amounts of nutrients and is essentially the food reserve that will feed the developing embryo and young sporophyte. Secondly, in grass (monocotyledon) species including cereal crops, the endosperm contains most of the nutrients that humans extract from the seeds. Wheat flour, for example, is essentially powdered endosperm. In broad-leaved flowering plants (eudicotyledons), however, the endosperm functions only during seed development and the nutrients are transferred to the *cotyledons* (seed leaves) during seed maturation. The outer layers of the ovule develop into the seed coat, which protects the seed during dormancy. After fertilization, the ovary tissues of the flower also undergo changes that will lead to it becoming a fruit. Fruits are unique to angiosperms, and often function in protection of the seeds, as well as in aiding their dispersal.

The evolution of diverse pollination strategies has been one of the keys to angiosperm success by improving the efficiency of pollen transfer from anthers to stigmas, dramatically reducing the amount of pollen (and resources needed to make pollen) required for reproductive success. While some angiosperms rely on abiotic means for this (wind and water) like gymnosperms, many have evolved specialized relationships with animal pollinators that transport pollen from one flower to another with much greater efficiency than abiotic factors. Indeed co-evolution with a wide variety of animal pollinators has driven much of the incredible variation we see in floral diversity.

A consequence of the evolution of flowers is that most species male and female organs are in close proximity. Left unchecked this creates a situation favoring inbreeding, which leads to a loss of genetic variability and reduces the potential of species to adapt to environmental change (Holsinger, 2000). Though many species do inbreed, notably weedy species this is regarded as a short-term evolutionary strategy and most have evolved one of a variety of outbreeding mechanisms. These mechanisms may be temporal (male and female structure maturing at different times), spatial (single sex flowers), combining both temporal and spatial (positioning of stigma and/or anthers change as flowers age to promote cross-pollination), or biochemical. The latter are broadly classed as “self-incompatibility” systems, by which the stigma or style of a plant can recognize and inhibit self- or genetically related pollen as it grows through it, preventing fertilization. Such outbreeding mechanisms have been estimated to

exist in as many as 70% of wild Angiosperm species and are hypothesized to have been key to the diversification and success of this group (Richards, 1997).

Asexual reproduction

A wide variety of forms of asexual reproduction are found in the flowering plants. The majority of these involve vegetative structures that can lead to propagation by fragmentation, for example the bulbs of crocuses and daffodils, rhizomes of irises and orchids, and stolons (runners) of strawberries. There are, however, a number of forms of asexual reproduction in this group that utilize at least some of the aspect of sexual reproduction, in particular seeds. The term apomixis is commonly used in reference to flowering plants to refer to the asexual production of seeds (*agamospermy*). Apomixis has been the subject of considerable study as it is of economic interest in regard to being able to heritably “fix” the F1 hybrid vigor that occurs in many higher plant species and is widely utilized in agriculture and horticulture to increase yield.

Based on the phenomenology of apomixis in different lineages (it occurs in at least 33 families), there are many different mechanisms through which asexual seeds can be produced and it has arisen multiple times during angiosperm evolution. It is beyond the scope of this article to go into detail on the many forms that apomixis may take, but a general theme is that though seeds are produced, the embryos they contain are formed not from a fertilized egg. These embryos may form from maternal cells that would have become the gametophyte but failed to complete meiosis and as a result are still diploid, or from maternal sporophytic cells that never entered meiosis. In either case the cells are diploid and form embryos without the need for fertilization by a sperm cell. In some instances the second fertilization event to form the endosperm is still a requirement for seed development, but the embryo itself is a clone of the maternal plant. Notable commercial angiosperms with apomixis are *Citrus* sp. and *Allium* sp. as well as one of the more vigorous and problematic weedy species *Taraxicum officinale* (Dandelions).

Penguins are sentinels of the marine environment, and by observing and studying them, researchers can learn about the rate and nature of changes occurring in the southern oceans. – P. Dee Boersma, PhD

Species & Distribution

Eighteen species of penguin breed south of the equator, and are broadly distributed across the southern hemisphere. Penguins breed in colonies that range in size from a few dozen to hundreds of thousands (Borboroglu and Boersma, 2013). The conservation status of Penguin species varies greatly. According to the IUCN, five species are endangered, five are vulnerable, three are near threatened and only five are considered least concern (IUCN, 2017). Understanding the breeding ecology of these species is vital to their conservation (Table 1).

Penguins breed in colonies of varying size across much of the southern hemisphere (Borboroglu and Boersma, 2013; IUCN, 2017). Penguins breed on both islands and on mainland Africa, South America, Antarctica, New Zealand and Australia (Fig. 1). Predation threats at these colonies vary considerably. For example, species breeding in Antarctica face considerable predation pressure from Leopard seals with little-to-no terrestrial threats, while Humboldt and Magellanic penguins face predation from fox and mountain lion species on land in S. America with few marine predators (Borboroglu and Boersma, 2013).

Penguin Reproduction

Penguins are unique among serially monogamous birds as they generally nest far from their food source, in colonies where they encounter complex social interactions and varied predators. When on land, many seabirds share parental time investment in chick rearing. During this time, they must exchange nest attendance, gaining metabolic resources to fast while incubating eggs and provisioning chicks.

Penguins in general are highly philopatric, returning to similar locations as their natal nest (Borboroglu and Boersma, 2013). A number of species migrate long distances during the non-breeding season, following food sources away from their breeding colony.

Table 1 Penguin species

Species name	Common name	Population trend	IUCN conservation status
<i>Aptenodytes forsteri</i>	Emperor Penguin	Unknown	Near Threatened
<i>Aptenodytes patagonicus</i>	King Penguin	Increasing	Least Concern
<i>Eudyptes chrysocome</i>	S. Rockhopper Penguin	Decreasing	Vulnerable
<i>Eudyptes chrysolophus</i>	Macaroni Penguin	Decreasing	Vulnerable
<i>Eudyptes moseleyi</i>	N. Rockhopper Penguin	Decreasing	Endangered
<i>Eudyptes pachyrhynchus</i>	Fiordland Penguin	Decreasing	Vulnerable
<i>Eudyptes robustus</i>	Snares Island Penguin	Stable	Vulnerable
<i>Eudyptes schlegeli</i>	Royal Penguin	Stable	Near Threatened
<i>Eudyptes sclateri</i>	Erect-crested Penguin	Decreasing	Endangered
<i>Eudyptula minor</i>	Little Penguin	Stable	Least Concern
<i>Megadyptes antipodes</i>	Yellow-eyed Penguin	Decreasing	Endangered
<i>Pygoscelis adeliae</i>	Adelie Penguin	Increasing	Least Concern
<i>Pygoscelis antarcticus</i>	Chinstrap Penguin	Decreasing	Least Concern
<i>Pygoscelis papua</i>	Gentoo Penguin	Stable	Least Concern
<i>Spheniscus demersus</i>	African Penguin	Decreasing	Endangered
<i>Spheniscus humboldti</i>	Humboldt Penguin	Unknown	Vulnerable
<i>Spheniscus magellanicus</i>	Magellanic Penguin	Decreasing	Near Threatened
<i>Spheniscus mendiculus</i>	Galapagos Penguin	Decreasing	Endangered

Penguin species name, common name, population trend and conservation status from IUCN, 2017. The IUCN Red List of Threatened Species. Version 2017-1. Available at: <http://www.iucnredlist.org>.

Fig. 1 Species Distribution. Penguins breed in both polar and temperate ecosystems and both on the islands and mainland of the Southern Hemisphere, species distribution from Borboroglu and Boersma. Data from: Borboroglu, P., Boersma, P.D. (Eds.), 2013. *Penguins: Natural History and Conservation*. Seattle & London: University of Washington Press. Base Map: Sean Baker – Free use, with attribution, under the CC-BY-2.0 license.

These distances vary greatly among species. Adelie penguins have the longest annual migration, some traveling distances over 8000 mi following prey assemblages, while Galapagos penguins remain at the archipelago (Borboroglu and Boersma, 2013). With climate change and migrating prey assemblages, young penguins will prospect and establish new colonies leading to a steady decline in previously large and stable populations (Borboroglu and Boersma, 2013).

There is variation in the seasonality of penguins breeding from highly constrained species like Magellanic, Adelie and Emperor penguins to Galapagos penguins that will breed and molt dependent on food resources. In general, penguins will return to breeding colonies from migrations where they spend weeks to months at sea. Many penguins will copulate at the colony after mates return from migration, though there is some evidence that penguins will copulate at sea and these copulation events can and do lead to successful fertilization. Upon returning to the colony, penguins undergo a settlement period where they secure and prepare nesting sites, court new mates and await return of former mates (Borboroglu and Boersma, 2013; Yorio *et al.*, 2001; Boersma *et al.*, 1990). Penguin nest types are generally defined by breeding habitat. Temperate species, on average, tend to nest in burrows or under bush cover. These nests provide both protection from terrestrial and avian predators, as well as favorable thermal conditions, helping to insulate young chicks from exposure (Fig. 2). Polar species, however, tend to nest on open ground. Some species, notably Chinstrap, Adelie and Gentoo penguins will gather material to elevate nests above ground level for incubation of eggs and chicks. Emperor penguins, however, will incubate eggs and chicks directly upon open ground and ice.

After settlement and copulation, fertilized eggs are laid. One or two eggs are laid depending on species, and for most penguin species, only one reproductive attempt is made yearly (Borboroglu and Boersma, 2013; Yorio *et al.*, 2001; Boersma *et al.*, 1990; Boersma and Rebstock, 2010). Some species, like Humboldt and Galapagos penguins, will lay secondary clutches in a year if eggs are lost before hatch or if reproductive conditions are optimal at the breeding colony (Borboroglu and Boersma, 2013).

Eggs range in size from Little blue penguin eggs measuring approximately 54×42 mm to Emperor penguin eggs at approximately 120×85 mm (Borboroglu and Boersma, 2013). Penguin eggs are also unusually thick among birds. Researchers believe this is due to the hard and rocky nesting conditions upon which penguins makes their nests (Boersma *et al.*, 2004). This shell thickness resists cracking during incubation and when adults exchange incubation duties. The shells of Magellanic penguins are particularly thick. Some are more than 56% thicker than eggs of birds of similar size (Borboroglu and Boersma, 2013; Boersma *et al.*, 2004). The food

Fig. 2 Magellanic penguins. Magellanic penguins during settlement at Punta Tombo, Argentina.

intake of most penguins however is not enough to supply the calcium needed to create these thick shells. To supplement this, female penguins appear to ingest small bivalves and mollusk shells to supply extra calcium to make these crack resistant eggs (Boersma *et al.*, 2004). In many species of penguin, first and second eggs vary in size, where the first egg is significantly larger than the second. The relationship however, is reversed in most *Eudyptes* penguins where the larger egg is laid second (Borboroglu and Boersma, 2013; Crossin *et al.*, 2012). In Macaroni penguins, there exists an extreme difference where the second egg is 60% larger than the first (Crossin *et al.*, 2012). In general, these larger eggs produce larger chicks and larger chicks tend to fledge at a significantly heavier weight and are more likely to survive and be seen as adults in the colony (Cerchiara *et al.*, 2017). This increased egg size also increases fledging success (Reid and Boersma, 1990). Penguin body condition can affect the size of these eggs as females that are better foragers, in better body condition, may have more resources to allocate to larger eggs.

Since penguins cannot feed on land, those individuals that arrived initially in poor body condition and must leave on foraging trips to self-provision in preparation for incubation bouts (Borboroglu and Boersma, 2013; Boersma, 2008). While mates are foraging, penguins incubate their egg(s) and protect offspring and nests from predators and conspecific competition (Borboroglu and Boersma, 2013; Yorio *et al.*, 2001; Boersma *et al.*, 1990; Boersma, 2008). Adult penguins will exchange incubation and brooding duties and these exchanges will occur more frequently as eggs mature and near hatching. In most species that lay more than one egg, viable eggs will hatch within a few hours to a few days of one another (Borboroglu and Boersma, 2013; Yorio *et al.*, 2001; Boersma *et al.*, 1990; Boersma and Rebstock, 2014). At this time it is critical that adults return from foraging with food ready to provision the chicks, as hatchling yolk sack may only provide nutrition to new chicks for a short time. Penguin chicks are termed semi-altricial. At hatch penguin chicks have limited mobility and, though downy, have limited thermoregulatory capacity (Borboroglu and Boersma, 2013; Yorio *et al.*, 2001; Boersma *et al.*, 1990; Boersma and Rebstock, 2014). It is during this period that adult penguins must incubate chicks, as they are under considerable risk of death from exposure, even in temperate penguin species. The frequency of storms can exacerbate this risk, flooding nests and soaking young chicks (Boersma and Rebstock, 2014). During the next few weeks, adults frequently attend nests during what is termed the *guard stage*. Young penguin chicks are under considerable mortality risk. During the guard stage, adults overlap between foraging trips to provision chicks, never leaving the chicks unattended. The metabolic needs of chicks, which are entirely dependent on their parents for food, increase with age, and movement of forage fish stocks affects the rate at which adults can deliver food to their chicks (Borboroglu and Boersma, 2013; Yorio *et al.*, 2001; Boersma, 2008). The amount, frequency and quality of food that the chicks receive depends on the quality of the parents, proximity of food stocks to the breeding colony, and food density. Unattended chicks are susceptible to increased risk of predation, exposure to temperature or severe weather, and also starvation. For chicks, primary mortality risk consists of thermoregulation and exposure, starvation and predation threat (Boersma and Rebstock, 2014). For many species the level of these risks vary throughout the breeding season.

During the guard stage, adults overlap between foraging trips to provision chicks, never leaving the chicks unattended. Due to the metabolic needs of the chicks, or movement of forage fish stocks, in some species the amount of time that adults overlap decreases until the point at which chicks are often left home alone in the nest for increasing amounts of time, a transition to the post-guard or *crèche stage*. After a few weeks of growth, penguin chicks are old enough that they are left home alone at the nest, during what is termed the post-guard or *crèche stage*. For small chicks, predation and thermoregulation may present the greatest risks, and starvation risk is diminished due to the low nutritional needs of very small offspring. At some point, however, these risks can shift. Older chicks may be large enough to limit their threat of predation through avoidance/evasion of predators and will benefit from a favorable surface area to volume ratio, diminishing their threat of exposure. However, larger chicks may have increased nutritional needs for metabolism and growth and therefore their risk of starvation may increase. It is during this time, penguin chicks will often *crèche*, or huddle together. Emperor penguins are well known to *crèche*, huddling together for warmth. Other penguins, including some temperate species, will minimize risk of predation through *crèche* behavior. As penguin chicks mature through *crèche stage*, they continue to gain mass and will begin to grow waterproofing juvenile feathers. It is during this stage that the foraging ability of adults can either mitigate or exacerbate starvation risk in larger penguin chicks.

Once feathering is complete, penguins have a defined juvenile plumage and are able to venture to the ocean. During the juvenile period, most penguins forage independent of their parents and are responsible for self-provisioning. Interestingly, Galapagos penguin parents have been recently observed feeding their juvenile offspring suggesting that post fledge provisioning may occur to support offspring in years of favorable food availability (Boersma *et al.*, 2017). Depending on the species, penguins will spend approximately one year in juvenile plumage after which they will haul out on land where they will lose all their juvenile feathers and grow feather of adult coloration (Borboroglu and Boersma, 2013).

Additional Threats to Penguin Chicks

In many colonies, starvation is the primary cause of mortality (Boersma and Rebstock, 2014). Overfishing, moving prey stocks, pollution, and climate change can all affect the ability of penguin adult to forage effectively to return to provision growing chicks. There are, however, additional environmental factors that can lead to chick mortality and result in a decrease in penguin fitness.

The second major cause of chick mortality is from predation. Penguin chicks are vulnerable to predation from both avian and terrestrial predators. Young chicks are under particular threat from avian predators. Other colonial seabirds, including species of gull, skua, and giant petrel, often breed among or near penguin colonies and will feed on small chicks and eggs. Cats, foxes, weasels and other mammals, as well as some reptiles (e.g. S. American armadillo) can predate larger penguin chicks while adults are away from the nest, even momentarily (Borboroglu and Boersma, 2013).

In some populations of penguins, diseases and parasites can infect and frequently kill penguin chicks. Blood, gastrointestinal and feather parasites are all known to affect penguin chicks of various species (Borboroglu and Boersma, 2013; Vanstreels *et al.*, 2016; Kleinertz *et al.*, 2014; Levin *et al.*, 2009). Blood parasites are among the most ubiquitous and significant parasites that infect penguin chicks. These parasites are spread primarily through invertebrate vectors and for this reason are more rare in wild colonies where these vectors are unlikely, like particularly cold and/or dry breeding sites (Vanstreels *et al.*, 2016). According to a review of blood parasites in penguins, only nine species had observed blood parasites, however, fifteen species were observed to be infected when in captivity or in rehabilitation centers (Vanstreels *et al.*, 2016). Gastrointestinal parasites and helminthes (worms) are ubiquitous among penguins, as well as the accumulation of alga toxins have also been observed in many breeding penguins (Kleinertz *et al.*, 2014; Shumway *et al.*, 2003). Algal blooms, commonly called red tides, are caused by dinoflagellates and are increasing in frequency across penguin habitat. Through bioaccumulation, toxins concentrate as alga are eaten by larger animals, eventually reaching harmful levels in prey eaten by penguins of all habitats (Borboroglu and Boersma, 2013; Shumway *et al.*, 2003). This can lead to the death of penguins and their chicks, and the frequency of these toxic blooms is increasing with climate change (Gobler *et al.*, 2017). Morbidity from these pathogens and parasites can directly impact the breeding success of penguins and risk large-scale mortality events in potentially struggling colonies.

One of the more interesting and puzzling conditions observed in growing penguin chicks is the appearance of featherless penguins. Initially observed at rehabilitation sites in S. Africa and breeding colonies in Argentina, featherless chick disorder appears in young Magellanic and African penguin chicks during the first few weeks of growth (Kane *et al.*, 2010) (Fig. 3). Penguins hatched normally feathered, however begin to lose feathers in patches until they become completely featherless. As they grow, chicks will begin growing adult feathers and can reach fledgling size. These chicks, however, have significantly slower growth curves and are smaller than feathered birds of the same age (Kane *et al.*, 2010). This suggests increased energetic needs of featherless chicks, likely due to thermoregulation (Kane *et al.*, 2010). Though the cause is unknown, scientists observed an increased occurrence in rehabilitation centers and believe a range of factors, from pathogens, to nutrient imbalance and pollution could cause the disorder (Kane *et al.*, 2010).

Conservation

Thirteen species of penguin are in population decline or under threat of extinction (IUCN, 2017). Penguins are under threat of climate change, overfishing of prey-stocks, destruction of breeding habitat and pollution (Borboroglu and Boersma, 2013; Boersma, 2008; Boersma and Rebstock, 2014; Rebstock *et al.*, 2016; Boersma *et al.*, 2015). Penguins, especially breeding populations, act as sentinel species informing us about the health of their local environment and also the greater ocean ecosystem (Boersma, 2008, 1974). Five penguin species are endangered, five are vulnerable, three are near-threatened and only five are considered least concern. There are a number of conservation efforts to protect breeding penguins during the reproductive season – the period when both adults and chicks are at the greatest risk and with the greatest influence on fitness and population growth. Establishing no-take, or managed marine protected areas (MPA) that extend not only to the terrestrial breeding colony, but also the marine foraging grounds is critical to protecting penguins (Boersma *et al.*, 2015; Pichegru *et al.*, 2010; Costello and Ballantine, 2015).

For temperate species of penguins, particularly those in S. America and Africa, the establishment of marine protected areas has proved difficult and therefore few MPAs exist. Those that do exist were established as the result of years of long-term research and data collection and have seen success in impacting penguins foraging ability; notably a no-take fishing closure for marine areas surrounding African penguins in S. Africa and Namibia (Pichegru *et al.*, 2010). Penguins were tracked via time-depth recorders and after only 3 months of implementation, 70% of penguin dives were less than 20 km away, within the protected marine area (Pichegru *et al.*, 2010). Penguins also had to expend less effort searching for food and their search time decreased by 30%, reducing daily energy expenditure by 40% (Pichegru *et al.*, 2010). A similar MPA was recently developed in Argentina to protect the world's largest breeding colony of Magellanic penguins at Punta Tombo, Argentina – a population currently facing a near 30% decline in the last 30 yrs (Borboroglu and Boersma, 2013; Boersma *et al.*, 2015).

The Ross Sea Marine Protected area, off the coast of Antarctica, is the world's largest MPA and protects the breeding and foraging grounds of Adelie and Emperor penguins and supports a no-fishing zone exceeding 432,000 square miles included within the MPAs total 598,000 square miles (CCAMLR, 2017). The establishments of this MPA highlights not only the successes in unilateral protection of the world's oceans, but also the difficulty in developing marine protected areas on the foraging grounds for stable populations of breeding penguins. Scientists from the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) initially proposed the MPA in 2011, after which years of scientific data helped refine the proposal. In 2016–2017, the two remaining hold-out countries (China and Russia) adopted the proposal, helping secure healthy breeding sites and prey assemblages for over 16,000 species that live in the Ross Sea, including polar penguins (CCAMLR, 2017).

Galapagos penguins are under particular threat of extinction; this species exists in only one population at the Galapagos Islands. These penguins are unique as they do not migrate and can breed year round, provided food resources are abundant enough to provision chicks (Borboroglu and Boersma, 2013; Boersma *et al.*, 2017; Boersma, 1974, 1978). Since these penguins do not follow food stocks, the success of their breeding and therefore the health of the species, depends directly on the health of oceans around the islands. The Galapagos Islands are uniquely placed, cold ocean currents, particularly the South Equatorial and Humboldt currents, jut out from the coast of S. America and bring nutrient rich waters to the islands (Borboroglu and Boersma, 2013; Boersma *et al.*, 2017; Boersma, 1974, 1978). In general, waters around the Galapagos are particularly rich with prey for penguins. For this reason, however, overfishing, as well as changes in ocean currents as a result of climate change, threatens the health of prey stocks (Borboroglu and Boersma, 2013; Boersma *et al.*, 2017; Boersma, 1974, 1978). To protect the prey that supports the penguins, and many other species of seabirds including the Blue-footed booby and Flightless cormorant, two no-take regions were developed to prevent fishing of the valuable food source (Borboroglu and Boersma, 2013). It is the hope that the establishment of these no-take zones, combined with efforts to expand usable breeding sites, will lead to increased reproduction and population growth for these endangered penguins.

Glossary

Androstenedione An androgenic steroid secreted by the ovaries and adrenals that is involved in the synthesis of testosterone.

Clitoris A small, sensitive erectile organ in the female corresponding to the male penis and located at the ventral end of the vulva.

Masculinize To cause an individual to develop the secondary sexual characteristics of a mature male, as by the natural exposure to or experimental administration of androgens.

Placenta A structure formed by fusion of the chorion with the wall of the uterus that serves to attach the embryo to the uterine wall and to exchange nutrients, wastes, and gases between the maternal blood and the embryonic blood.

Prohormone A precursor of a hormone.

Sexual differentiation The process by which the two sexes become different; whereby a bi-potential embryo develops along either male or female lines, as determined initially by the chromosomes and subsequently by hormones.

Spotted hyena A social carnivore of the family Hyenidae.

The Family Hyenidae

Hyenidae, a lineage that separated from viverrid ancestors 25–30 million years ago, comprises four extant species (**Fig. 1**): the aardwolf (*Proteles cristatus*), the striped hyena (*Hyaena hyaena*), the brown hyena (*Parahyaena brunnea*), and the spotted hyena (*Crocuta crocuta*). Although there is substantial variation in the details of their social and mating systems, gestation and development, parental care and feeding ecology (**Table 1**), the first three of these species present traditional, sexually dimorphic, external genitalia. In the fourth species, the spotted hyena, females exhibit remarkably ‘masculinized’ external genitalia. Because of the extraordinary similarity in *Crocuta* between male and female genital morphology, the common belief that these animals were hermaphrodites persisted well into the 19th century. More recently, it was discovered that female spotted hyenas also exhibit a suite of behavior patterns conventionally associated with a ‘masculine’ phenotype, being unusually aggressive, playing more roughly than males, scent marking in the same manner as males, and totally dominating adult males in social situations. This array of ‘masculine’ characteristics has directed attention to the process of sexual differentiation in the female spotted hyena: Either there are androgens circulating during fetal life that create the unusual external genitalia of these animals (and might enhance their ‘masculine’ behavior), or there is a hitherto unrecognized mechanism for the production of male-like genital morphology in a female mammal. The present article is, accordingly, focused on reproduction and sexual differentiation in the spotted hyena, although we begin with a brief outline of the major features of reproductive biology in the four extant hyenid species.

Reproduction in the Hyenidae – An Overview

Despite their phylogenetic divergence, all four hyenid species have commonalities in their reproductive biology and behavior (**Table 1**). For instance, all males lack a baculum. Both sexes of all species have anal scent glands contained within an anal pouch,

Fig. 1 Three of four living members of Hyenidae, including the (A) striped hyena, (B) brown hyena, and (C) spotted hyena. Photographs by C. M. Drea.

Table 1 Comparative reproductive biology and life histories of hyenids

Features	Hyenid species			
	<i>Aardwolf</i> (<i>Proteles cristatus</i>)	<i>Striped</i> (<i>Hyaena hyaena</i>)	<i>Brown</i> (<i>Parahyaena brunnea</i>)	<i>Spotted</i> (<i>Crocuta crocuta</i>)
Age at maturity (y)	M=1.8 F=1.8	M=2–3 F=2–3	M=1.8 F=1.5–2	M=2 F=3
Lifespan (y)	Wild: 7 Captive: 15	Wild: 15 Captive: 24	Wild: 12 Captive: 20	Wild: 20–25 Captive: >40
Size differentiation	Size monomorphism			Reverse size dimorphism
Adult mass (kg)	M=7.8–14 F=7.7–14	M=28.0–43.2 F=27.5–36.0	M=35–49.5 F=28–47.5	M=40–62.5 F=44–90.0

Interlitter interval (mo)	12	14	12–41	16–19

^aFemale brown hyenas mate with nongroup-living males, whereas female spotted hyenas mate with group-living males.

and engage in ‘pasting’ (and other forms of scent-marking behavior); the deposited chemical signals play a role in sexual and reproductive advertisement (Fig. 2). Lastly, although the physical structure varies depending on the environment, all species make use of natal dens to protect their young (Fig. 3). Regarding generalizations on reproduction, the similarities across species end here. Teat number varies individually and by species. Notably, in spotted hyenas, there is only a single pair of teats, a factor contributing to sibling rivalry in triplet litters. Also, only spotted hyenas show sexual size dimorphism favoring the female, and only female *Crocuta* display highly ‘masculinized’ sexual organs (see below). In all other hyenids, adults are sexually size monomorphic and the adult female sexual organs are not ‘masculinized.’

Fig. 2 Hyena olfactory communication. (A) A spotted hyena extrudes its anal pouch while straddling a blade of grass, depositing glandular secretions in a behavior termed ‘pasting.’ (B) The trademark, pasted scent mark of a brown hyena comprises chemically distinct ‘white’ and ‘brown’ components, deposited in close succession. (C) Spotted hyenas engaged in intense social sniffing of conspecific paste from a non-clan member. Photographs by C.M. Drea.

Fig. 3 Hyena dens. (A) Caves and crevices on the Namibian coast serve as a natal den for brown hyenas. (B) Bones accumulate at the den's entrance owing to the adult members of brown hyena clans provisioning cubs. (C) Abandoned aardvark burrows serve as a communal den for spotted hyenas in South Africa; the cub, which is still nursing, is seen transitioning from its black natal coat to its adult spotted coat. Photographs by C.M. Drea.

The Aardwolf

For such a small family, hyenids show fairly diverse reproductive behavior and mating strategies, from monogamy to promiscuity. The least typical member of Hyenidae, the aardwolf, is socially monogamous, forming pair bonds that can last anywhere from two to five years; however, both sexes are known to engage in extra-pair copulations. Aardwolves are the smallest, the shortest lived, and the only seasonal breeders among Hyenidae. Females generally have a single yearly estrous in July (although if not fertilized they will cycle a second time about two weeks later) and give birth in October to litters of one to four cubs. Because of this species' exclusive termite diet, cubs are entirely dependent on maternal milk for the first four months of life. Although male partners, even if cuckolded, guard and defend the young, they do not provide them with food.

Striped Hyenas and Brown Hyenas

Striped and brown hyenas are the most closely related and, consequently, the most similar in their reproductive biology. They are of roughly equal size and longevity, and have similar lifestyles in that both are solitary foragers and scavengers. In contrast to the aardwolf, these two species are aseasonal breeders, with females being polyestrous. Neonatal mass in striped and brown hyenas is at least threefold that in the aardwolf, but cubs of all three species are born with their eyes closed. Although striped and brown hyenas have multiple pairs of teats, only the two caudal pairs are functional.

The most prominent differences in reproduction between striped and brown hyenas are evidenced by adult behavior. Although behaviorally solitary, for breeding purposes striped hyenas form short-term, pair bonds or even polyandrous groups of up to three adult males per single adult female. Multiple paternity is likely and the resulting 'family' unit may endure for several years. There is biparental care as both sexes provision the young. The 'single family' approach of striped hyenas contrasts with the 'cooperative venture' of brown hyenas. The latter occur in small social groups in which members are related to each other. Females mate with nongroup-living, nomadic males; nevertheless, resident males provide care for the young they did not sire. Mothers are also cooperative, suckling the cubs of other females along with their own. All clan members participate in provisioning of the cubs (see Fig. 3(B)).

The Spotted Hyena

Unlike their relatives, spotted hyenas are pack hunters and live in the largest social groups of any carnivore. Within this complex social network, there is no extended pair-bonding of the sort seen in other hyenas: Mating is promiscuous and there is no paternal care. Spotted hyenas are aseasonal breeders, but there is little information on their estrous cycle. They are currently the only known member of Carnivora in which pregnant females develop hemochorial placentas. They have an exceptionally long gestation (of approximately 110 days) and their young are unusually precocial at birth (see below). Despite this 'head start,' spotted hyenas have longer lactation periods than do most other carnivores, which places a substantial energetic burden on mothers and by extension, puts lower-ranking females at a disadvantage. Not surprisingly, therefore, mothers generally suckle their own young exclusively. Details of spotted hyena reproductive biology are described below.

Reproduction in the Spotted Hyena

Morphology

In the female spotted hyena, the clitoris has hypertrophied, approximating the size and shape of the male's penis; it is fully erectile, allowing her to display erections similar to those of the male (Fig. 4(A) and (B)). Erections serve an important communicatory function and are used by both sexes in ritualized 'greeting' ceremonies (Fig. 4(C)). Uniquely, the elongated clitoris is traversed

Fig. 4 The erections of male and female spotted hyenas. The erect (A) penis and (B) clitoris are comparable in size and shape, and are used by both sexes, at all ages, in (C) species-specific, social 'greeting' ceremonies. Photographs by L.G. Frank, reprinted with permission.

by a central urogenital canal, through which the female urinates, copulates, and gives birth. There is no 'external' vaginal opening: The labia have fused to form a pseudoscrotum, marked by two pads of fibrous/fatty tissue that are outwardly visible and might be mistaken for testes. The internal reproductive system follows the standard mammalian pattern.

Careful visual examination of the external genitalia reveals sex differences in 'phallic' structure. Notably, the clitoris is shorter and thicker than the penis. The shape of the glans is also sexually dimorphic: The glans penis has an angular profile, whereas the glans clitoridis has a rounded contour (**Fig. 4(A) and (B)**). These visible differences in the shape of the glans are now used by field researchers to distinguish male from female spotted hyenas. Lastly, the central urogenital canal ends in an opening (the urogenital meatus) that is larger and more elastic in the female than in the male. Internally, based on histological examination, the female urogenital canal is pleated and unconstrained by erectile or connective tissue, allowing for significant expansion that would not be afforded the male. This elasticity is prerequisite for mating and birth, and is facilitated in adulthood by the actions of estrogens and the peptide hormone relaxin.

These structural differences emerge much earlier in development, however (**Fig. 5**). Although there are no sex differences in either the internal or external morphology of male and female genital tubercles at 30–34 days of fetal life, major differences in internal phallic structure are identifiable at 45–50 days of gestation when the fetal gonads are morphologically differentiated. As gestation proceeds, a thick, fibrous tunica completely envelops the corpus spongiosum and urethra of the developing male and prevents expansion of the urethra (**Fig. 5(A)**). In the developing female, however, a tunica envelops only the corporal body (**Fig. 5(B)**), thus later permitting expansion of the urogenital sinus during mating and parturition. These functionally significant sex differences, noted previously in adult spotted hyenas, are dependent upon testicular androgens in males, and are present at birth.

Fig. 5 Sexual dimorphism and feminization of the internal 'phallic' structures of neonatal spotted hyenas. Mid-shaft sections through the phallus of a (A) normal male, (B) normal female, and (C) a male treated with anti-androgens. Specimens #21 and #20 (A and B) were obtained at 95 days of gestation and specimen #23 (C) was obtained at 105 days. In A and B, respectively, the sexually differentiated structures include the urethra (Ur) vs. the urogenital sinus (UGS), the presence vs. absence of the corpus spongiosum (CS), the size and expanse of the tunica (Tu), and the position of the retractor muscles (denoted by black arrows). Prenatal anti-androgen treatment of males caused dramatic feminization of these structures (C). Photographs by G.R. Cunha, modified with permission.

Mating Behavior

Mating occurs in the social context of the hyena clan. Unlike the social canids, in which breeding is commonly restricted to the dominant female, all female spotted hyenas mate and give birth; nevertheless, their social standing within the clan influences their success at rearing offspring to independence. Females typically achieve sexual maturity at 24–36 months of age and reproduce in the clan of their birth. Males generally disperse at the time of puberty (at 18–24 months) and mate only after joining a new clan. At present, little is known of the spotted hyena estrous or ovulatory cycle (if, in fact, there is a cycle). The presence of spines on the glans penis of spotted hyenas is characteristic of other species that are induced ovulators, suggesting the possibility of induced ovulation in spotted hyenas. Although there are seasonal peaks in the frequency of births, associated with rainy seasons in sub-Saharan Africa, there is no sharply defined breeding season and mating occurs throughout the year.

Because of their unusual external anatomy, the act of mating requires patience and cooperation on the part of the female, as well as some temerity and agility on the part of the male (Fig. 6). During the sexual act, the female retracts her clitoris into the abdomen and, standing exceptionally still, assumes a head-down posture. The male mounts the female and stands on his hind legs with his forepaws on her flanks (Fig. 6(A)). He then ‘flips’ his erect penis against her lower abdomen (Fig. 6(B)), searching for the clitoral opening (Fig. 6(C)), which is well anterior to the position normally occupied by the external vagina (Fig. 6(D)). To achieve entry, the male must squat down on his haunches, move forward, and reposition his pelvis (Fig. 6(E)). After achieving entry there is an interval of pelvic thrusting followed by ejaculation. During the minutes following ejaculation, the male maintains insertion and often assumes a posture in which he leans forward resting his head on the back of the female. A number of additional ejaculatory sequences may follow, with the female taking an active role in soliciting the male’s attention.

Gestation and Parturition

Relative to the other hyenids, gestation is prolonged in the spotted hyena. Concentrations of plasma progesterone increase within the first two weeks and, as pregnancy proceeds, plasma concentrations of estrogen, testosterone, and relaxin also show a substantial rise from pre-pregnancy values. A marked increase in the size of the nipples is often the first external indicator of pregnancy, particularly in primiparous animals. In nature, as the female proceeds toward term, she locates a site removed from the communal den of the clan and gives birth at this ‘natal den’ (see Fig. 3). The young will be nursed and maintained at this den for a variable period (2–4 weeks) before being carried by the mother to the communal den and introduced to the clan.

Costs of Clitoral Delivery

Giving birth to a large (1–2 kg) fetus through the clitoris is a mechanically challenging feat (Fig. 7(A)). The urogenital meatus, although highly elastic, is not adequately large to permit passage of the fetus and must tear before an initial birth can occur (Fig. 7(B)). The process is further complicated by the presence of a short umbilical cord and a rather tortuous route from the point of placental attachment in a uterine horn. The fetus must travel through the uterus and upper vagina before finally reaching the clitoris. If delivery of the fetus does not proceed in a timely fashion, the infant will be stillborn (presumably due to anoxia, consequent to detachment of the placenta from the uterine wall). In captivity, approximately 60% of first births result in stillborn offspring due to the time required for passage of the fetus. Moreover, in some captive, primiparous females, the fetus became lodged in the birth canal and, without veterinary intervention, would have taken the life of the mother. Similar complications may explain the loss of primiparous female hyenas in nature. In subsequent pregnancies, after a fetus has successfully passed through and torn the clitoris, infant mortality (and indeed maternal mortality) is much lower. Because there are substantial costs to clitoral delivery in this species, it is probably not surprising that this process has evolved only once.

Behavior of Infants

The twins that generally constitute a hyena litter are quite precocial. At birth, their eyes are open, they have substantial locomotor skills, and they possess an impressive array of needle-like teeth (Fig. 7(C)). In addition, within minutes of the birth of the second cub, the twins begin to fight. The fighting between siblings is intense and, if uninterrupted, wounds result from the vigorous biting. At a minimum, fighting during the first days of life establishes a dominance relationship between the siblings that lasts minimally for several years. In nature, if the dominant sibling can keep its young twin sequestered in a burrow and prevent it from emerging to nurse, death will result from a combination of starvation, wounding, and infection. When siblicide occurs, it has been found to be based on resource availability, as in other species displaying this behavior. If both infants survive, however, the intense aggression is largely replaced by playful, prosocial interactions. The development of prosocial behavior is also on a precocial timeline, emerging in the second week of life and increasing over subsequent months. This schedule ensures that both aggressive and prosocial behavior patterns will be established within the infant’s repertoire when it joins the clan. As outlined below, the exposure of all fetuses to high concentrations of androgens during fetal life might be expected to facilitate the aggression observed at birth in this species.

Fig. 6 The mating sequence in spotted hyenas. (A) The male mounts the female, who stands still, with her head lowered and her clitoris retracted into her abdomen. (B) The male shows penile 'flips,' as indicated by arrows. (C) Underside view and (D) lateral view of a female spotted hyena, with arrows showing the site of the clitoral opening, which is located far anterior to the point of entry in other female mammals. (E) Once the male locates the opening, he squats down and scoots forward to enable intromission, which is followed by pelvic thrusting. Illustrations by C.M. Drea, reprinted with permission.

(B) Delivery cannot progress until the clitoris tears, the delay often leading to fetal hypoxia and stillbirth. (C) Live cubs are precocial at birth. Photographs by S.E. Glickman, and L.G. Frank, reprinted with permission.

Sexual Differentiation in the Spotted Hyena

The Search for Androgens in Adult Female Hyenas

Contemporary understanding of sexual differentiation requires the secretion of androgens, by the fetal testes, for the production of masculine external genitalia from embryological precursors. Such androgens are also known to affect the developing nervous system, modifying hypothalamic mechanisms responsible for sex-typical profiles of hormone secretion, as well as structures modulating sexually dimorphic behavior patterns. Given the exceptionally 'masculine' external genitalia of the female spotted hyena observed at birth, it is not surprising that early research was directed toward a search for raised testosterone concentrations in females. The size, aggressiveness, and dominance of these animals also suggested that substantial concentrations of this androgen might be found in adult females. It soon became clear, however, that non-pregnant, adult female hyenas have relatively low plasma concentrations of testosterone. By contrast, androstenedione, primarily of ovarian origin, is the primary androgen found in high concentrations in female spotted hyenas. Androstenedione is an interesting steroid. It is known to bind with low affinity, if at all, to conventional estrogen or androgen receptors, but it is readily converted to an active estrogen or to testosterone in the presence of appropriate enzymes. Following conversion, androstenedione could exert powerful hormonal effects on a developing fetus or on the postnatal nervous system.

The Search for Androgens in Fetal Hyenas

In all mammals studied to date, the fetal testes secrete androgens during embryonic life that result in the formation of male genitalia; fetal ovaries are typically found to be inactive during fetal life and, in the absence of androgens, a female genital phenotype emerges. In the spotted hyena, both the fetal testes and fetal ovaries are active during the embryonic period, and are capable of secreting androgens; however, based on anatomical studies, it is clear that both the penis and the penile clitoris are fully formed at an early stage (before 36 days) of gestation, prior to maturation of the fetal gonads. The fetal testes are capable of androgenic secretion before the fetal ovaries, and such earlier secretions presumably account for the major differences in internal and external penile/clitoral morphology present at birth.

In addition to the fetal gonads, it appears that the placenta of the spotted hyena is a significant source of androgen from an early stage of gestation. A clue as to potential sources of fetal testosterone was provided by the high concentrations of this steroid observed in the circulation of pregnant hyenas. It seemed possible that the gradual increment in maternal testosterone concentration during pregnancy reflected two processes: the metabolic conversion of maternal ovarian androstenedione to testosterone by the placenta, and; the absolute growth in size of this structure during the course of gestation. Subsequent studies of placental activity supported this hypothesis and verified that maternal androstenedione, converted to testosterone in the placenta, was transferred to the developing fetus via the umbilical circulation (and the maternal circulation via the uterine venous drainage of the placenta).

A mechanism was thus in place that could account for masculinization of the external genitalia in this unique species. This possibility was reinforced by the appearance of several human cases in which genetic female infants were born with masculinized genitalia due to a defect in aromatase activity, i.e., a defect in which an abnormal human placenta acted, metabolically, like a normal hyena placenta; however, recent studies suggest that the essential penile/clitoral phenotype is formed before placental androgen production could be involved in formation of these organs.

Evidence for Significant Non-Androgenic Processes During Prenatal and Postnatal Life

The possibility that non-androgenic mechanisms account for formation of the penis/clitoris in the spotted hyena was tested by interfering with the putative action of gonadal or placental testosterone on the developing fetus of both sexes. Anti-androgens administered to pregnant female dogs during appropriate stages of pregnancy result in their male offspring having a very small penis, a urethral opening near the base rather than the tip of the penis (i.e., hypospadias), and a blind vaginal pouch in the midline of the scrotal area. By contrast, anti-androgens (flutamide and finasteride) administered to pregnant female spotted hyenas had a rather different phenotypic effect. Male offspring exposed to these compounds as early as day 12 of gestation were indeed 'feminized,' but their genitalia now approximated those of a normal female spotted hyena, rather than those of a generic female mammal. Such males had a short, thick penis with a large urogenital meatus and the glans was rounded like the glans clitoridis (as in Fig. 4(B)), rather than angular like a normal glans penis (as in Fig. 4(A)). Moreover, the size and shape of the urethra (or urogenital sinus) in the absence of a corpus spongiosum, the size and expanse of the tunica, and the position of the retractor muscles in these males (Fig. 5(C)) corresponded to features of normal female spotted hyenas (Fig. 5(B)). Female offspring exposed to anti-androgens prenatally were still more 'feminized,' with an exceptionally short, thick clitoris and a still larger urogenital sinus. In sum, the data from anti-androgen experiments suggest that androgens normally modulate fetal development in both male and female spotted hyenas. However, the robust development of a penis or penile clitoris from the genital tubercle, and a fully formed scrotum from the genital swellings, in the absence of androgenic activity, suggests that a non-androgenic mechanism may be involved in the initial formation of these structures.

Recent studies, involving the administration of letrozole to pregnant female spotted hyenas, suggest a role for estrogens in formation of the penile and clitoral shaft that encloses the urethra in both sexes. Letrozole interferes with the aromatase enzyme required for production of estrogens. Embryos collected from letrozole-treated pregnant females, as well as infants born to

letrozole-treated mothers, displayed incomplete fusion of epithelial tissues on the ventral surface of the penis or clitoris, as required for the urethra to be a fully enclosed structure.

Further evidence for the existence of androgen-independent mechanisms regulating the growth of the clitoris and the penis is provided by examining the effects of pre-pubertal gonadectomy. In other mammalian species, there is typically a period of accelerated growth of the genitalia accompanying puberty. Moreover, castration or ovariectomy prior to puberty inhibits such growth. Both in male and female spotted hyenas, the normal growth curve actually decelerates during puberty, with more rapid development both of genitalia and overall body size occurring prior to the pubertal period. Pre-pubertal gonadectomy causes a major reduction in adult concentrations of androstenedione and testosterone, suggesting that the ovaries, not the adrenal glands, are the primary source of androstenedione in female spotted hyenas; however, there are modest effects of such surgery on growth of the clitoris or penis (aside from some changes in the elasticity and thickness of the clitoris, which are normally induced by the presence of estrogens in females).

Summary – Mechanisms and Implications of Sexual Differentiation in the Spotted Hyena

Sexual Differentiation and Development: Integration of Androgenic and Androgen-Independent Mechanisms

It appears that both androgenic and non-androgenic mechanisms are involved in the development of the penile clitoris of the female spotted hyena. The basic formation of the clitoris, including enclosure of the urethra within the genital tubercle, can apparently proceed without the intervention of androgens; however, gonadal and placental androgens play a role in the early development of the clitoris and penis *in utero*. Paradoxically, the changes produced in the normal hyena clitoris by naturally circulating testosterone (i.e., a smaller urogenital sinus and opening and a thinner clitoris) serve to make a very difficult initial parturition still more costly.

General Implications From an Unusual Animal

Despite the very unusual events that underlie formation of the clitoris and scrotum in the spotted hyena, the contemporary theory of sexual differentiation survives intact. That theory was always an explanation of how one arrives at a male phenotype instead of a female phenotype for each species. Presumably, the sex differences in genital morphology observed in spotted hyenas at birth are the result of both placental and testicular testosterone acting on the male embryo, while only placental testosterone is circulating in the female embryo. Further separation of male and female genital morphology is produced by the different hormonal environments that are present postnatally, particularly the activity of estrogens in the female, but not in the male. Consideration of the spotted hyena calls attention to the absence of a substantive theory of feminine development. There is wide variation in mammalian clitoral morphology. Such species as lemurs and European moles also display varying degrees of clitoral 'masculinization.' To date, development of female genitalia often has been treated as a passive process. This situation must change in the future.

Studies of the spotted hyena also highlight the potential significance of androstenedione as a significant prohormone in all female (and male) mammals. Often dismissed in the contemporary literature as a 'weak androgen,' studies of the spotted hyena and other species (e.g., the redwing blackbird and meerkat) demonstrate the capacity of androstenedione to act as a very powerful steroid following conversion to estrogen or testosterone.

Finally, the role of placental metabolism is typically ignored in accounts of sexual differentiation. After all, within a species, the effects of that metabolism are assumed to be the same for male and female fetuses. This oversight may be rectified in the future, as the recent accounts of human pseudohermaphroditism, produced by a defect in placental aromatase activity, direct attention to the impact of placental metabolism on development. Studies of the hyena also emphasize the role of species differences in placental metabolism in modulating structural development in embryos of both sexes. Examination of 'experiments-of-nature,' such as the spotted hyena, reveal common processes in other, less exotic, species.

Glossary

Anamniotic Egg-laying vertebrates that do not produce an amniotic egg; fish and amphibians.

Archosaurian Belonging to the amniote lineage Archosauria, which includes dinosaurs, crocodilians, and birds; contrasts with Lepidosauria, which includes non-crocodilian reptiles (squamates).

Folliculogenesis The process of development, in which a female germ cell matures into a large haploid oocyte, surrounded by supporting granulosa and thecal cell layers.

Genital ridge Embryonic structure, precursor to the gonad.

Granulosa cell Female somatic support cell that immediately surround oocytes, responsible for estrogen synthesis and promotion of early ovarian development.

Intromittent organ Phallus or penis, used for sperm delivery in species with internal fertilization.

Lacunae Large spaces or cavities in the medullary region of the ovary of birds, crocodilians, and other reptiles.

Leydig cell Male somatic support cell in the testis, responsible for androgen synthesis.

Multiple paternity Phenomenon of a single clutch of eggs that are fertilized by sperm from more than one father.

Neonate Hatchling crocodilian.

Oocyte Female germ cell, egg.

Pod or crèche Group of hatchlings and/or young crocodilians.

Primordial germ cell (PGC) Germ cells that will migrate into the genital ridge and become either oocytes or spermatogonia.

Sertoli cell Male somatic support cell in the testis, responsible for controlling spermatogonia development and promotion of early testis development.

Spermatogonial stem cells Germ cells in males that give rise to sperm cells.

Steroidogenic Capable of producing steroid hormone(s).

Testis cord, medullary sex cord Embryonic structure in the testis that will develop into seminiferous tubules.

Theca cell Female somatic support cell that also surround oocytes, derived from granulosa cells, responsible for androgen synthesis.

Thermosensitive period Window of development during which the embryonic gonad is sensitive to temperature in sex determination; temperature cues outside this window do not effect sex.

Thermosensitivity Sensitivity to temperature in the context of sex determination during embryogenesis.

TSD Temperature-dependent sex determination, a mode of environmental sex determination where the temperature experienced during a window of embryogenesis determines sex of offspring.

Natural History of Crocodilian Reproduction

Crocodilians are globally distributed in tropical and subtropical areas, found on every continent excluding Europe and Antarctica. The International Union for Conservation of Nature recognizes 24 extant species of crocodilians within the order Crocodylia, with seven of these species listed as endangered or critically endangered. Crocodilians are spread across three families, including: Alligatoridae, which encompasses alligators and caiman; Crocodylidae, which includes all crocodiles; and Gavialidae, which includes only a single species, the gharial (*Gavialis gangeticus*) (although some lines of evidence suggest that a member of Crocodylidae, *Tomistoma schlegelii*, or the false gharial, is more closely related to the gharial than to crocodiles). Members of family Alligatoridae are found predominantly in the Americas, with the single exception being the Chinese alligator (*Alligator sinensis*), which is found exclusively in China. In contrast, members of Crocodylidae are found across the Americas, Asia, and Africa, while the single member of Gavialidae is found only on the Indian subcontinent. Despite their global distribution, all crocodilians are characterized by a shared reproductive biology and ecology that includes hierarchical social structures, complex reproductive behaviors, environmental sex determination, and Archosaurian reproductive traits. In this article we review this shared biology, discussing aspects of crocodilian nesting ecology, sex determination, and the reproductive tract. In the following section, we begin with a review of selected characteristics of crocodilian reproductive and nesting ecology, describing (1)

crocodilian mating systems and courtship and (2) nesting ecology, focusing on types of nests built by crocodilians and parental behavior during and after nesting.

Mating Dynamics

Hierarchies and male competition

Mating systems of crocodilians are characterized as polygamous male-dominated hierarchies, in which sexually mature males will compete for and establish territories, permitting access to receptive females. In this system, dominant males will typically mate with multiple females in a single year. In most crocodilians, environmental cues serve as triggers of breeding behavior. In subtropical species, increasing spring temperatures can cue reproduction, while equatorial species rely more heavily on hydrologic cycle periodicity (rainy/dry season transitions). The age and size at sexual maturity for male crocodilians varies by species, and the time required to reach maturity ranges from 10–18 years, although it can be lesser for species that reach maturity at smaller sizes. However, intrasexual competition among males promotes systems where only the largest, dominant individuals will successfully breed each year, leaving smaller males, while technically sexually mature, with few or no breeding opportunities. For example, male American alligators (*Alligator mississippiensis*) in some habitats reach maturity at 1.8 m (approximately 6 ft), but only males >2.7 m (approximately 9 ft) are expected to breed in a given reproductive season (Lance, 1989). In these competitive interactions, dominant males establish territories and preclude other males from entering and mating with females in that area. Males of some species will also actively patrol their territory during breeding season to engage competitors.

In contrast to males, female crocodilians typically reach sexual maturity at smaller sizes and most do not engage in the same intrasexual competition that would preclude younger females from breeding. Although, captive female American alligators have been reported to aggressively defend their future nest sites against other females, and captive female American crocodiles (*Crocodylus acutus*) can form female hierarchies, similar to males. Female American alligators reach sexual maturity at approximately 1.8 m, however, young females generally produce smaller clutches than older individuals. So, while females might become sexually mature at 10–16 years of age, their maximum reproductive potential may not be reached until >20 years (Lance, 1989). Additionally, not every mature female (or male) will breed each year. While the likelihood of nesting in a year increases with body size, estimates of the annual proportion of nesting alligators in Florida range from 16%–58% of adult females in a population (Lance, 1989), and females produce only a single clutch of eggs each year that they breed. However, the reproductive life span of an individual female can be quite lengthy, with long term data from American alligators suggesting that females can successfully reproduce for 30–40 years after reaching maturity (Wilkinson *et al.*, 2016).

Courtship behavior

Courtship in crocodilians involves a complex series of behaviors that can include vocal displays and responses and coordinated physical exchanges. Generally, a male will use a series of vocal displays (bellowing, head slapping, roaring) to attract receptive females to his territory, to which females may respond with their own vocalizations. Once in close physical proximity, male and female pairs engage in snout-snout and snout-neck contact and make a series of coughing exhalations. These initial displays are usually followed by a series of guided, circling swims lead by either sex, riding, additional snout contact, and bubble-blowing. If courtship is successful and neither party disengages, copulation will usually follow (Garrick and Lang, 1977). The physical act of copulation can last minutes and entails the insertion of the male penis-like intromittent organ into the cloaca of the female, permitting gamete transfer and fertilization. Crocodilians also possess two pairs of secretory glands (the gular glands on the lower jaw and the paracloacal glands in the cloaca) that produce secretions that are thought to be involved in reproduction, but the exact role of these glands and their secretions is not well understood in the context of courtship behavior, copulation, or nesting.

Multiple paternity

Despite territorial dominance and aggressive intrasexual competition among males, a mounting body of evidence supports the polygamous nature of crocodilian mating systems. Genetic analyses have uncovered clutches of eggs fertilized by multiple males (as many as four) in a number of crocodilian species, indicating the possibility that female crocodilians are also promiscuous. This multiple paternity could be driven by either 1) females mating with more than one male in a single season and using sperm from multiple mates to fertilize a single clutch of eggs; 2) females mating with a single male each season, but storing sperm from previous year(s) and using sperm from multiple years to fertilize a single clutch; or 3) both. Multiple paternity is likely a widespread phenomenon, and has been documented in the American alligator, Chinese alligator, estuarine (or saltwater) crocodile (*Crocodylus porosus*), Morelet's crocodile (*Crocodylus moreletii*), broad-snouted caiman (*Caiman latirostris*), Orinoco crocodile (*Crocodylus intermedius*), black caiman (*Melanosuchus niger*), and spectacled caiman (*Caiman crocodilus*).

Nesting Ecology

Nesting strategy

Approximately 3 weeks to one month following copulation, females lay a clutch of 20–40 eggs, although clutch size is strongly influenced by individual body size and age, as well as species. Average clutch size in American alligator in some populations can range from 40–60 eggs, with the largest clutch ever recorded containing 91 eggs (although this “single” clutch could have been

produced by two females sharing a single nest). In contrast, the African dwarf crocodile (*Osteolemus tetrapsis*) regularly produces clutches of 10 eggs or fewer. Egg size also varies with species; female gharial produce the largest eggs of any crocodilian (~160 g), while the Chinese alligator produces much smaller eggs (~50 g).

Crocodilian nesting strategy can be classified as either mound-nesters or cavity-nesters, and the choice in strategy seems to be influenced by habitat type. Species inhabiting forested riparian zones or wetlands regularly build nest mounds consisting of vegetation and soil, while species inhabiting riverine or marine systems deposit eggs in cavities excavated on sandy beaches. All species, however, choose nesting sites within close proximity to water. Mound-nesting species include the American and Chinese alligators, all caiman species, and several crocodiles, including the estuarine, New Guinea (*Crocodylus novaguineae*), and Orinoco crocodile, the false gharial and, in certain habitat types, the American and Cuban crocodile (*Crocodylus rhombifer*) (these species can build both types of nests). Hole-nesting species include the gharial, the freshwater crocodile (*Crocodylus johnstoni*) and the Nile crocodile (*Crocodylus niloticus*). Generally, members of family Crocodylidae display greater diversity in nesting strategy, as both mound and cavity nesting is found in crocodiles. In comparison, all members of Alligatoridae are mound nesters and the single member of Gavialidae, the gharial, is a hole nester.

Temperature and nesting

The temperature eggs experience during incubation is critically important to crocodilians, as all species studied to date exhibit temperature-dependent sex determination (discussed in greater detail in [Section The Crocodilian Sex Determination System](#)). In this system, sex of the developing embryo is determined by temperature, rather than by genetic factors or sex chromosomes. Both cool and warm temperatures drive offspring to develop as females, while intermediate temperatures promote the development of males. The exact range of temperature promoting development of the different sexes varies subtly from species to species, and exact thermal ranges are not known for all crocodilians. Temperature also influences the time required for eggs to hatch, as warmer nests will promote faster growth and development of embryos. Eggs typically require anywhere from 60–70 days to hatch once laid, although this varies among species and may require as long as 90–115 days.

Adult behavior during nesting

During the incubation period, females of many crocodilian species will remain in close proximity to the nest, both guarding it from predators and waiting to excavate hatchlings. Female American alligators will frequently remain in nearby ponds or holes and advance upon intruders in defensive displays that include open-mouthed charging and hissing vocalizations. Some female crocodilians will also regularly attend the nest, climbing on top and crossing over it several times and will repair the nest if damaged or disturbed by predators. Nest defense and attendance varies within and among species, and the purpose of the latter (beyond protection from predators and excavation of young) is not fully understood. Despite nest guarding, predation of nests is still a common occurrence in most crocodilian species, and both mammals and reptiles represent a persistent threat to nesting success. Flooding presents an additional natural threat to crocodilian nests, however habitat loss or destruction due to anthropogenic activity likely presents a much greater existential threat to crocodilian nesting than flooding or predators.

At the conclusion of the incubation period and, in response to collective vocalizations from hatchlings, females of most species will excavate nests with their mouths and forelimbs to assist hatchlings in exiting the nest. And, in some cases, the maternal female will grasp unhatched or partially hatched eggs in her jaws and assist in hatching by gently manipulating and cracking eggs with her teeth. In addition, the female will often carry hatchlings in her mouth to nearby water. Like nest defense and attendance, these behaviors vary within and among species, but some form of nest attendance or care is likely uniform to all crocodilians. Once hatching is complete, neonates will frequently remain in groups, termed pods, near the nest site for one year or more, staying in close proximity to maternal female for protection. Adult care for neonates is most commonly exhibited by the laying female, however, adult male Gharial will frequently guard large groups (100–1000s), called creches, of mixed-clutch and mixed-year neonates and juveniles, guarding them for many months after hatching occurs. This behavior is not frequently observed in adult males of other species, however, and cannibalism of hatchlings and juveniles by adults is common.

The Crocodilian Sex Determination System

All crocodilian species studied to date display a version of environmental sex determination that is regulated by the temperature that embryos experience during development. The key aspects of the crocodilian temperature dependent sex determination (TSD) system are reviewed below and include: (1) developmental timing of thermosensitivity, (2) the crocodilian TSD molecular network and (3) the influence of hormones on TSD ([Fig. 1](#)).

The Developmental Timing of Thermosensitivity

Ferguson and Joanen first described TSD in crocodilians in 1982 and demonstrated the adjustable nature of the alligator sex determination system ([Ferguson and Joanen, 1982](#)). This study along with others established the pattern of TSD in the American alligator (*Alligator mississippiensis*) along a gradient of increasing temperatures as female-male-female, with females being produced at extremes of the viable temperature range (below 31°C and above 34°C) and males produced at intermediate temperatures (32°C) ([Fig. 2\(A\)](#)). Mixed sex ratios are expected from temperatures between the male and female producing temperatures. Variation in

Fig. 1 Comparison of mound and hole nesting in *A. mississippiensis* and *C. acutus*. Representative images of an unopened (A) and opened (C) mound nests of *A. mississippiensis* in coastal South Carolina (United States). Nests are built from surrounding vegetation and soil, and eggs are deposited in the center of the mound, covered, and left to develop. For comparison, images of an unopened (covered in a mesh screen; B) and opened (D) hole nests of *C. acutus* from the Tempisque Basin (Costa Rica), where the maternal female excavates a cavity in the soil, deposits, and then covers her eggs. the sex ratios amongst different clutches incubated at identical non-extreme temperatures indicates that relative clutch effects also contribute to the equation that dictates how temperature impacts crocodilian sex determination (Lang and Andrews, 1994). The specific period of thermosensitivity in all reptiles displaying TSD is thought to encompass the embryonic stages during which the developmental trajectory of the bipotential gonad splits resulting in either a testis or an ovary. After the sexual differentiation of the gonad progresses beyond a specific developmental threshold, the sex of that individual is irreversibly established and the thermosensitive window is permanently closed. The specific period and associated developmental stages that characterize the opening of the thermosensitive window are not as clearly defined, likely a result of the practical variation in experimental techniques and the criteria used to define the window of sensitivity to incubation temperatures.

Knowledge regarding the temporal and developmental features of thermosensitivity originates primarily from detailed studies in the American alligator and involves thermal shift experimental designs. These design schemes incorporate the incubation of embryos at male- and female- producing temperatures (MPT and FPT, respectively). Single shift designs involve moving eggs from one temperature to the other at different developmental stages and are often used to broadly identify the pattern (FME, MF, etc.) and the temperature sensitive period (TSP). Double shift designs allow for examination of how sex ratios are affected by temporary pulses of a MPT against the background of a lower FPT and vice versa during different developmental periods. In 1994, Lang and Andrews applied both single- and double-temperature shift experiments to refine the period of thermosensitivity in *A. mississippiensis* and demonstrated that irrespective of incubation temperature, a discrete thermosensitive period that occurs from embryonic stage 21–24 (approximately 30–45 days of incubation) and encompasses the period of gonadal differentiation (Lang and Andrews, 1994). The period of development between embryonic stages 21 and 24 has served as the canonical period

Fig. 2 The thermosensitive period of sex determination in crocodilians. (A) Several crocodilian species display the female-male-female (FMF) pattern of sex determination. Extreme temperatures (below 32°C and above 34°C) produce primarily females and intermediate temperatures (between 32 and 34°C) produce primarily males. (B) The thermosensitive window of sex determination in crocodilians initiates as early as stage 15 of embryonic development and persists until the period of gonadal differentiation (stage 24).

of thermosensitivity in the American alligator and numerous studies have incorporated this specific period into designs aimed at characterizing the origins and mechanisms of temperature dependent sex determination. Subsequent thermal shift experiments, however, have challenged the discrete nature of this window and show that the thermosensitive period for the American alligator initiates by embryonic stage 15 of development, six stages prior than previously reported (McCoy *et al.*, 2015) (Fig. 2(B)). This finding further highlights the context dependent nature of the temperature dependent sex determination system in crocodilians.

The Crocodilian TSD Molecular Network

The morphological features of the adult testis and ovary display a remarkable degree of conservation across amniotes. This observed morphological conservation has prompted targeted investigations aimed at elucidating the molecular cascade that translates temperature into sex. Many of the key regulatory molecules involved in mammalian sex determination also appear to regulate sex determination in crocodilians. Sex determining region Y (SRY)-box 9 (SOX9) mRNA is expressed in alligator embryos and its abundance increases in gonads incubated at the MPT. SOX9 is a conserved transcription factor that promotes Sertoli cell differentiation and testis development. In mammals, SOX9 is directly downstream of the male determining factor, SRY. Reptiles and other non-mammals, however, lack SRY and the precise mechanisms by which SOX9 is regulated in these species remain elusive. Temperature-induced alternative splicing is involved in Indian mugger (*Crocodilus palustris*) gonadal sex determination and results in a female version of the Sox9 transcript that is not translated into a functional protein, thereby limiting its ability to induce testis development (Agrawal *et al.*, 2009). Further investigations are needed to determine how prevalent this mechanism is across other crocodilian species. Anti-Müllerian hormone (AMH), another key regulator of testis differentiation, is also expressed in alligator during the thermosensitive period. The regulatory mechanisms that govern the expression of AMH during testis development remain unclear for American alligator *in ovo*, although SOX9 can induce AMH transcription *in vitro*.

Conserved genes involved in ovarian differentiation have also been identified in crocodilians including aromatase (*CYP19A1*), forkhead box L2 (*FOXL2*), and R-spondin 1 (*RSPO1*). The sequencing and assembly of the American alligator genome has helped to overcome many of the technical challenges associated with genetic studies of non-traditional model organisms and will provide additional insights into the puzzle of temperature dependent sex determination.

The Influence of Hormones on Crocodilian TSD

It is evident that hormones also play central roles in promoting ovarian differentiation in TSD. In cases where estradiol is applied exogenously to eggs incubated at MPT, the process of testis differentiation is completely overridden and females are

produced. In the American alligator, estrogen activation of estrogen receptor- α (ESR1) appears to be sufficient, but not necessary for instigating the most upstream steps of ovarian development based in part on the expression profile of aromatase, the catalytic enzyme responsible for estrogen production, which is not detected until after the first morphological signs of gonadal differentiation occur (Parrott *et al.*, 2014). Many persistent contaminants found in the environment are categorized as endocrine disrupting chemicals (EDCs) due to their ability to impact the endogenous endocrine system. Exposure to EDCs during hormone-sensitive developmental windows can promote permanent alterations in reproductive system function. The nature of the crocodilian sex determination system makes it inherently sensitive to environmental factors (temperature, humidity, contaminants, etc.). This feature, along with other key aspects of crocodilian life history, warrant these species as exceptional wildlife sentinels for environmental health.

The Crocodilian Reproductive System

Gonadogenesis

As in other vertebrates, the gonads of crocodilians originate as a genital ridge, develop into bipotential gonads, and after sex determination differentiate into testes in males and ovaries in females. Primordial germ cell (PGC) specification and migration has not yet been observed in crocodilians due to experimental difficulties, but based on their shared Archosaurian lineage they are expected to follow the patterns seen in birds; namely, PGC specification follows the predetermined mode and the cells migrate through the bloodstream to arrive in the genital ridge at Ferguson stage 2 of development (Kohn *et al.*, 2014).

In *Alligator mississippiensis*, gonads develop in complex with the adrenal gland and the embryonic kidney (gonadal-adrenal-mesonephros complex, or GAM). The germinal epithelium and underlying medullary sex cords are observable by stage 12, and by stage 20 the bipotential gonads exhibit a distinct cortex containing PGCs. The earliest signs of gonadal sexual differentiation occur during the thermosensitive window of TSD, with observable presumptive Sertoli cells at stage 21 in the gonads of embryos incubated at the MPT, and germ cell proliferation in the gonadal cortex at stage 22 in embryos incubated at the FPT (Smith and Joss, 1993).

Sexually dimorphic gonadal differentiation continues throughout the rest of embryonic development. In the testes, the germinal epithelium diminishes and germ cells disperse into the medulla, where seminiferous cords become more organized, with well-defined Sertoli cells (Smith and Joss, 1993). In contrast, the ovarian cortex becomes more defined, characterized by proliferating germ cells, while lacunae form in the fragmenting medulla (Smith and Joss, 1993). Oocytes develop in the cortex, enclosed by granulosa cells and steroidogenic theca cells. The caudal portion of the ovary, known as the medullary rest, does not follow this pattern but instead exhibits the dense arrangement of medullary sex cords seen in the testis (Forbes, 1940).

Adult Gonadal Structure and Function

Full maturation of the gonads of crocodilians, as with birds, continues post-hatching. Unlike birds, however, crocodilian ovaries maintain a reserve of cortical oogonial nests rather than converting all oogonia into primary oocytes during gonadal maturation, and thus can produce new follicles throughout their lifetime (Kohn *et al.*, 2014). The lacunae that develop in the medullary stroma are characterized by a framework of collagen and smooth muscle, and may function to facilitate follicular expansion. The signaling processes guiding folliculogenesis in crocodilians have not yet been fully elucidated, but developmental exposure to environmental estrogens disrupts the process, resulting in multi-oocytic follicles (Guillette *et al.*, 1994).

The adult crocodilian testis exhibits the tubular morphology characteristic of amniotes, with highly convoluted seminiferous tubules lined with an epithelium of Sertoli cells. The testosterone-generating Leydig cells of the testis localize around cord structures and mature sperm are typically replenished throughout reproductive life due to the persistence of mitotic spermatogonial stem cells. In *A. mississippiensis*, spermatogenesis begins in early spring, and germ cells mature in a single cohort to produce one continuous spermiation event during the breeding season from May-June, which differs from the consistent spatial developmental pattern of spermatogenesis observed in other amniotes. This temporal pattern is reminiscent of spermatogenesis in anamniotic amphibians, but was also documented in two other seasonally breeding reptile species, the slider turtle (*Trachemys scripta*) and the European wall lizard (*Podarcis muralis*), suggesting that the testes of crocodilians and these other reptiles are transitional between the anamniotic and amniotic testis (Gribbins *et al.*, 2006).

Adult Gonadal Structure and Function

Full maturation of the gonads of crocodilians, as with birds, continues post-hatching. Unlike birds, however, crocodilian ovaries maintain a reserve of cortical oogonial nests rather than converting all oogonia into primary oocytes during gonadal maturation, and thus can produce new follicles throughout their lifetime (Kohn *et al.*, 2014). The lacunae that develop in the medullary stroma are characterized by a framework of collagen and smooth muscle, and may function to facilitate follicular expansion. The signaling processes guiding folliculogenesis in crocodilians have not yet been fully elucidated, but developmental exposure to environmental estrogens disrupts the process, resulting in multi-oocytic follicles (Guillette *et al.*, 1994).

The adult crocodilian testis exhibits the tubular morphology characteristic of amniotes, with highly convoluted seminiferous tubules lined with an epithelium of Sertoli cells. The testosterone-generating Leydig cells of the testis localize around cord structures

and mature sperm are typically replenished throughout reproductive life due to the persistence of spermatogonial stem cells. In *A. mississippiensis*, spermatogenesis begins in early spring, and germ cells mature in a single cohort to produce one continuous spermiation event during the breeding season from May–June, which differs from the consistent spatial developmental pattern of spermatogenesis observed in other amniotes, including birds. This temporal pattern is reminiscent of spermatogenesis in anamniotic amphibians, but was also documented in two other seasonally breeding reptile species, the slider turtle (*Trachemys scripta*) and the European wall lizard (*Podarcis muralis*), suggesting that the testes of crocodilians and these other reptiles are transitional between the anamniotic and amniotic testis (Gribbins *et al.*, 2006).

Reproductive Tract Structure and Function

The crocodilian female reproductive tract, or oviduct, is highly functionally and structurally regionalized. Whereas the oviducts of other reptiles produce both the fibrous proteins that form the eggshell membrane and the outer calcareous layer of the eggshell in one uterine region sequentially, crocodilians and other Archosaurs have two spatially distinct regions, complete with distinct glandular structures (Palmer and Guillette, 1992). Thus crocodilian eggs can be packaged in an “assembly line” fashion, an evolutionary adaptation that has been seen as an innovation allowing for flight in birds, although birds process eggs through their oviducts one at a time, whereas crocodilians process an entire clutch at once.

When reproductively active, the oviduct is highly responsive to estrogen stimulation, undergoing dramatic increases in size and extensive glandular development for producing the necessary secretory products for proper egg packaging (Palmer and Guillette, 1992). As in other vertebrates, the oviducts originate from the embryonic Müllerian ducts. After gonadal sex determination, Müllerian ducts regress in males due to the influence of AMH, but they are fully retained in females, and unlike in birds, both mature into functional adult oviducts.

In contrast to female reproductive structures and function, the male reproductive tract has not been well studied in crocodilians. However, male extra-gonadal reproductive structures are generally similar to mammals and birds, with the ductus deferens linking the testes to the phallus for gamete transfer (although the crocodilian phallus is distinct from both mammalian and avian structures). The crocodilian ductus deferens serves to collect, store, and deliver sperm from the epididymis and seminiferous tubules within the testes during breeding season. Crocodilians appear to lack a dedicated accessory secretory gland for production of seminal fluid. However, evidence is beginning to emerge that multiple regions of the male reproductive tract may contribute to seminal secretions. In spectacled caiman, the morphological and histochemical properties of the epididymis and ductus deferens suggest its involvement in the production and modification of seminal fluid, and structural characteristics at the gross morphological, cellular, and ultrastructural levels are highly similar to birds, more so than to other reptiles, supporting the Archosaurian lineage of crocodilians. (Guerrero *et al.*, 2004).

These findings in caiman have been corroborated by recent work in the American alligator that have reported the presence of exocrine glands in the male phallus that likely contribute secretions during reproduction to form seminal fluid. The crocodilian phallus is itself a highly specialized and complex structure, characterized by three distinct morphological regions: the tip, cuff, and base, and an open groove, termed the sulcus or penile groove, for sperm delivery. During copulation, it is likely that increased blood flow to vascular regions surrounding the sulcus close it into a complete tube, while coordinated smooth muscle contractions promote sperm movement into the female reproductive tract (Moore *et al.*, 2012). Unlike mammalian or avian penile structures, most of the crocodilian phallus is rigid, containing dense collagenous regions, and only a small region is erectile. The phallus is also retained within the cloaca until copulation occurs, when it is everted for intromission into the female (Moore and Kelly, 2015).

Elephants

Janine L Brown, Smithsonian Conservation Biology Institute, Front Royal, VA, United States

Introduction

Elephants are important ambassadors for global conservation: they are keystone species that have a major impact on ecosystems; they are umbrella species that indirectly protect other species in its habitat; and as iconic flagship species, they raise awareness for action and funding of broader conservation efforts. Despite their importance, however, wild elephants are threatened (African) or endangered (Asian) throughout their natural ranges because of habitat destruction, human-elephant conflict, and poaching for ivory, skin and other products. The future of both species ultimately depends on whether humans and elephants can learn to coexist peacefully in the same environment, although effective solutions have so far remained elusive. As wild elephant numbers decline, captive breeding may be viewed as a means to maintain important populations as “insurance” against environmental or anthropomorphic catastrophe. So long as they are self-sustaining, and not replenished by wild capture, *ex situ* populations also offer opportunities to study elephant biology in ways that are not possible in the wild, and provide information that can aid *in situ* conservation.

Several aspects of female elephant reproduction differ from other mammals, including luteal steroidogenic activity, pituitary gonadotropin secretion, fetal development and reproductive tract morphology, while males exhibit the unique phenomenon of musth and an unusual reproductive anatomy (internal testes, ampullary semen storage). The finding of notable species differences in biological mechanisms (e.g., prolactin secretion, gestational steroid patterns, sperm cryosensitivity) and problems associated with uterine pathologies and ovarian acyclicity means that inferences from one species to another should be made cautiously.

Female Reproduction

General Reproductive Biology

Elephants are polyestrous, and exhibit the longest spontaneous cycle of any mammal: 13–17 weeks in duration, with a 4- to 7-week follicular phase, and an 8- to 10-week luteal phase (see review, Brown (2014), Fig. 1). Unlike most mammals, the major

steroid produced by the corpus luteum (CL) is not progesterone, but 5α -reduced pregnanes (e.g., 5α -pregnane-3,20-dione, 5α -pregnane-3-ol-20-one, 17α -hydroxyprogesterone), herein referred to as 'progestagens.' Estradiol is low in circulation due to rapid conjugation and urinary excretion (Czekala *et al.*, 2003), and thus is of limited use for characterizing follicular cycles. While elephants are easily trained for blood collection to track ovarian activity, some aspects also can be assessed noninvasively; for example, analysis of progestagens in saliva, feces and urine, and estrogen conjugates in urine (Wasser *et al.*, 1996; Czekala *et al.*, 2003). Females reach puberty between 10 and 14 years of age in the wild, but can mature earlier in captivity (Sukumar, 2003; Glaeser *et al.*, 2012), perhaps because of improved nutrition. It is not uncommon for Asian elephants to begin cycling as young as 5 years of age, with the first pubertal rise in progestagens being quantitatively and qualitatively similar to subsequent cycles (Glaeser *et al.*, 2012; Fig. 2).

Elephants also have the longest gestation period of any mammal, lasting 20–23 months on average (Figs. 2 and 3), and typically give birth to a single offspring. Calves weight 90–120 kg at birth, with males generally being heavier. Lactational anestrus lasts for 8–12 months, and the inter-birth interval ranges between 4 and 6 years, depending upon resource availability. Calves nurse for up to 5 years, so females can be pregnant and lactating at the same time. Elephants are not obligatory seasonal breeders; however, conception rates often are higher during or shortly after peak rainfall in seasonal regions, and can be negatively affected by drought (Sukumar, 2003; Wittemyer *et al.*, 2007). Elephants are capable of reproducing into their 50's, although conception rates decline with age and the inter-birth intervals lengthen. There is no evidence that elephants experience a true 'menopause' like that in humans (Lahdenperä *et al.*, 2014).

Anatomy

The elephant has the longest reproductive tract of any land mammal, approximately 3 m from vulva to ovary, and has been well-described (Hildebrandt *et al.*, 2000, 2003, 2006, 2011, 2012a; Fig. 4). Unusual features of the female urogenital tract are: (1) a long vestibule that averages 1.3 m in length and opens ventrally between the hind legs; (2) a permanent hymenal membrane in nulliparous females with a small vaginal os (4 mm×2 mm in diameter) that ruptures only during parturition; and (3) two blind pouches of similar size on either side of the vaginal opening. The vagina is up to 50 m in length, consists of longitudinal folds, and produces mucus during estrus. The mix of excreted urine and mucus contains pheromones that attract bulls to estrous females. The cervix is about 10 cm long and has a prominent cone-shaped opening. Semen is deposited into the vagina through the vaginal os, often resulting in retrograde semen loss after mating. After 8 weeks of gestation, a thick vaginal mucus plug is formed that provides

a protective barrier against infective agents. The uterus is bicornuate, with a short body (<10 cm) and long uterine horns (>60 cm). Implantation takes place in one of the uterine horns. On the rare occasion of twins, fetuses are found in each horn. The oviducts are ~10 cm long. Paired ovaries, located behind the kidneys, are proportionally small (5.5–6.5 cm).

Ovarian Cycle

Most of our knowledge about the female elephant ovarian cycle is based on hormonal and ultrasound assessments (Lueders *et al.*, 2010, 2011; Brown, 2014). A model of the ovarian cycle is presented in Fig. 1. A distinguishing feature is the “double LH surge” that is observed in both species: two precisely timed luteinizing hormone (LH) surges associated with follicular waves that occur 3 weeks (18–22 days) apart during the follicular phase, referred to as LH1 (anovulatory) and LH2 (ovulatory) (African: Kapustin *et al.*, 1996; Asian: Brown *et al.*, 1999). The surges are quantitatively and qualitatively similar, and generally are more distinct in Asian elephants. During the first wave, multiple follicles develop, but none ovulate (Hermes *et al.*, 2000). Instead they luteinize and become accessory CL (acCL) (Lueders *et al.*, 2010). During the second wave, a new group of follicles develop, but only one becomes dominant, ovulates and forms a single, ovulatory CL (ovCL). All CLs are present throughout the follicular phase, with some of the larger ones remaining in subsequent luteal periods (Lueders *et al.*, 2010). Formation of multiple CLs in addition to the ovulatory CL may be a mechanism to ensure there is sufficient luteal capacity for sustaining a long gestation should conception occur.

Inhibin follows a distinct pattern in elephants (Brown *et al.*, 1991; Kaewmanee *et al.*, 2011a; Lueders *et al.*, 2011; Yamamoto *et al.*, 2012a). In other species, both small and large estrogenic follicles are significant sources of inhibin. However, in the elephant, circulating inhibin does not increase until after follicle luteinization post LH1, about 9 days before LH2 (Fig. 1), suggesting it is the cells of luteinized follicles and acCLs that are the main source of inhibin. Inhibin also is increased during the luteal phase; immunohistochemical staining has localized inhibin subunits to the lutein cells of CLs, similar to that in primates (Yamamoto *et al.*, 1991, 1992). Follicle-stimulating hormone (FSH) secretion is inversely related to inhibin throughout the cycle in both elephant species (Brown *et al.*, 1991, 1999; Kaewmanee *et al.*, 2011a; Fig. 1). It is highest toward the end of the luteal phase and throughout the first follicular wave when inhibin is low, then decreases to nadir concentrations before LH2 as inhibin is rising. The FSH pattern in elephants, albeit more protracted, is similar to that of the horse, with high concentrations at the end of the luteal phase that decline progressively towards ovulation (Brown *et al.*, 1991, 1999; Kaewmanee *et al.*, 2011a). This prolonged FSH stimulation may be necessary to induce the two successive follicular waves. In the face of declining FSH, the transition of one follicle from an FSH-dependent to an independent state likely is needed for dominant follicle selection, as described in other species.

Prolactin is folliculogenic in many species (Freeman *et al.*, 2000; Frasier and Gibori, 2003), and in African elephants is elevated during the follicular phase of the cycle (Yamamoto *et al.*, 2010; Dow and Brown, 2012; Fig. 5). Interestingly, no secretory prolactin pattern is observed across the estrous cycle in Asian elephants (Brown *et al.*, 2004a). As discussed later, this species difference may explain why ovarian cycle problems related to abnormal prolactin secretion are common in African, but not Asian elephants. Recently, cortisol has been shown to exhibit a distinct pattern in both species, with concentrations being higher during the follicular phase (Fanson *et al.*, 2014), the importance of which is unknown.

Fig. 4 Schematic diagram of the reproductive tract of the female elephant: (a) KD, lobulated kidney; RE, rectum. (b) OV, ovaries; UT, uterus bicornis; CE, cervix; VA, vagina; VO, vaginal os with two bilateral blind pouches; VE, vestibule; UB, urinary bladder; UR, urethra; PB, pelvic bone. Aspects of the reproductive biology and breeding management of Asian and African elephants. *Int Zoo Yrbk* 40, 20–40.

Both species advertise impending fertility, albeit through different chemical signals. Female Asian elephants excrete a urinary signal, (Z)-7-dodecenyl acetate (Z7-12: Ac) that stimulates male breeding behavior, the concentrations of which increase during the follicular phase and peak just before ovulation (Rasmussen *et al.*, 1997; Rasmussen, 2001). African elephants do not produce Z7-12: Ac, but excrete frontalin, exo-brevicomin, endo-brevicomin, (E,E)-alpha-farnesene and (E)-beta-farnesene in urine leading up to and during estrus (Goodwin *et al.*, 2006). Considering the long distances bulls travel in search of estrous females in the wild, a prolonged pattern of pheromonal signaling would be a beneficial strategy for species survival.

Pregnancy

Endocrinology

In the elephant, acCLs are produced throughout the follicular phase of preceding cycles (Lueders *et al.*, 2010, 2011), but there are no additional CLs produced during gestation (Lueders *et al.*, 2012). Based on histology and analysis of luteal progestagens, the corpus

Fig. 5 Longitudinal profiles showing the relationship between progesterone and prolactin secretion in a normal cycling female African elephant.

luteum of pregnancy appears to be the most steroidogenically active between 3 and 15 months of gestation. This period is characterized by progesterone concentrations that on average are higher than those during the non-pregnant luteal phase (Meyer *et al.*, 2004; Lueders *et al.*, 2012; Figs. 2 and 3). In both species, acCLs and the ovCL begin to regress about 5–6 weeks after conception (the normal luteal phase lifespan). They then rebound and grow significantly larger than CL during a non-conceptive luteal phase, in conjunction with a marked secondary rise in progesterone concentrations and presumed implantation (Meyer *et al.*, 2004; Lueders *et al.*, 2012). Inhibin also is elevated during the first 8 weeks, as in a normal luteal phase. But in contrast to progesterone, which rebound to even higher concentrations, inhibin declines and remains at baseline throughout gestation (Yamamoto *et al.*, 2012a; Fig. 3). This pattern suggests a shift in CL function between cycling and pregnant elephants, and that a role for inhibin in pregnancy is unlikely. After 5–7 months, both relaxin and prolactin markedly increase (Meyer *et al.*, 2004; Yamamoto *et al.*, 2012b; Fig. 3). Prolactin remains elevated throughout, whereas the relaxin profile is biphasic and concentrations start to decline after mid-gestation, with a secondary surge at parturition (Meyer *et al.*, 2004). To date, no evidence of any gestational gonadotropin-like activity in serum or placental extracts has been found.

There are some notable species differences in gestational hormone patterns. Progesterone concentrations are higher in African elephants during the first half of gestation, but then decline to levels below those observed in Asian elephants (Meyer *et al.*, 2004). There also is a fetal gender effect on progesterone patterns, but only in Asian elephants; females carrying male calves produce more progesterone as compared to those carrying females (Meyer *et al.*, 2004). It is possible to sex the fetus after about a year of gestation with near 100% accuracy in Asian elephants by measuring circulating maternal testosterone, which presumably is of testicular origin and higher in females carrying a male calf (Duer *et al.*, 2002; Brown *et al.*, 2004b). This fetal-sexing technique is less accurate in African elephants. Parturition can be predicted on the basis of a rapid fall in progesterone about 2–5 days before birth (Brown and Lehnhardt, 1995; Carden *et al.*, 1998). Surges in cortisol often are observed in the last 2 weeks of gestation, with a significant surge at parturition (Meyer *et al.*, 2004).

Placentation and implantation

The placenta is chorioallantoic, zonary endotheliochorial with some hemochorial regions (see reviews, Allen (2006); Hildebrandt *et al.* (2006)). Implantation is central and superficial, with a mesometrial orientation of the yolk sac, and antimesometrial orientation of the embryo, and occurs during the second to third month (Drews *et al.*, 2008). Longitudinal transrectal ultrasound has identified an initial period of comparatively slow embryonic development in both elephant species (Hildebrandt *et al.*, 2006; Drews *et al.*, 2008). The embryonic vesicle is visible at ~8 weeks post-conception, which is smaller (~10 mm) than that of other species at that stage (cattle, 40 mm; sheep, 70 mm; horse, 40 mm). Likewise, time of implantation is estimated to be ≤ 20 days in human, dog and sheep, but ≥ 50 days in the elephant. The fetus then doubles in size between the fourth and fifth month, and at 8 months drops into the abdominal cavity and no longer is visible by transrectal ultrasound. Permanent uterine scars are formed by the invasive attachment of the placenta, which allows quantifying the number of pregnancies by ultrasound or at necropsy.

Parturition and lactational anestrus

Hermes *et al.* (2008) has reviewed the current knowledge of elephant obstetrics. A week or more before parturition, the female may begin showing signs of discomfort, while passage of the vaginal mucus plug or mucoid discharge occurs in the days leading up to parturition. Once labor begins, the female becomes restless and changes positions often. Abdominal contractions increase in frequency, but may not always be visually evident. The cervical canal becomes dilated by pressure from the allantoic sac during labor, followed by partial emergence of fetal legs entering the vaginal cavity. A large bulge appears under the tail, initially consisting

of the fluid-containing amniotic sac, but eventually the calf crests the caudal rim of the pelvis and slips out between the elephant's hind legs. Active labor and delivery is relatively short: 2–4 h. The majority of births are in the posterior position. Dystocia is not uncommon in captive elephants, and is related to excessive body weight, advanced age, lack of exercise, urogenital track pathologies, anterior presentation of the calf, and large calf size. In zoos, nulliparous females are generally considered post-reproductive after ~30 years of age because of a greater risk of dystocia and stillbirth. If labor stalls, oxytocin can be administered, but only after confirming the cervix is sufficiently relaxed and the calf is in the birth canal.

The length of the post-partum anestrus period generally lasts 12–24 months (e.g., Fig. 2). Problems with retained placenta, reduced milk production, death of a calf, or premature weaning can reduce the post-partum period to as short as 8 weeks (Brown, 2000). The first luteal phase increase in progestagens after the lactational anestrus period, when cycles resume, is similar to subsequent ones (Glaeser *et al.*, 2012; Fig. 2).

Reproductive Problems

Ovarian acyclicity

Reproductive problems of captive elephants are well documented, and for Africans in particular, a high rate of ovarian acyclicity across the age categories thwarts population sustainability (Brown, 2014). In North America, 52% of African elephant females exhibit abnormal cycles, with 38% not cycling at all (Brown *et al.*, 2016). Comparatively, the acyclicity rate in Asian elephants is lower (<20%) and affects mostly older females (Dow *et al.*, 2011a; Brown *et al.*, 2016). Several conditions known to be associated with infertility in other species are not related to ovarian cycle problems in African elephants, such as hyperandrogenism, hyperestrogenism, thyroid derangements, pituitary dysfunction and elevated cortisol (Brown, 2014). The finding of no differences between cycling and acyclic elephants in anti-müllerian hormone (AMH) concentrations suggests the problem is not due to a lack of functional follicles (Dow *et al.*, 2011b). One association with ovarian acyclicity in African elephants is hyperprolactinemia (Brown *et al.*, 2004a; Yamamoto *et al.*, 2010; Dow and Brown, 2012), which is the most common disorder of the hypothalamic-pituitary axis related to infertility in women (Serri *et al.*, 2003; Wang *et al.*, 2012). Over half of noncycling elephants exhibit levels of prolactin that are 5- to 30-fold higher than those in normal cycling females. As in other species, pituitary prolactin secretion in elephants is under inhibitory control by dopamine (Brown, 2014). The dopamine agonist, cabergoline, effectively suppresses prolactin secretion in hyperprolactinemic elephants, but has yet to induce a resumption of ovarian cyclicity even after a year of treatment (Morfeld *et al.*, 2014a). No underlying physiological cause of hyperprolactinemia has yet been found, but it does not appear to be related to abnormal production of cortisol, estradiol or thyroid hormones (TSH, T₃, T₄) (Brown *et al.*, 2004a,b). Asian elephant females rarely present with hyperprolactinemia (Brown *et al.*, 2004a,b), representing a significant species difference.

Several studies in the United States and Europe have applied epidemiological methods to identify factors in the zoo environment that are associated with reproductive success, and noted several differences between Asian and African elephants (Harris *et al.*, 2008; Brown *et al.*, 2016). For both species, the chance a female will cycle is greater when they are housed in a mixed-sex herd, and decreases with age. For African elephants, social stability and compatibility, and enrichment are important for promoting normal pituitary-ovarian function, whereas social isolation has a negative effect. Behaviorally, dominant females identified as herd peacekeepers often are more likely to be acyclic (Freeman *et al.*, 2004). There also appears to be a social aspect to hyperprolactinemia in African elephants, which is more prevalent in females exposed to many social groups throughout the day, and perhaps related to social instability (Brown *et al.*, 2016). Another finding is that the majority of zoo Asian and African elephants are overweight (Harris *et al.*, 2008; Morfeld and Brown, 2014b), and in Africans, a high body mass index and body condition score has been related to acyclicity, metabolic hormone (insulin and the glucose to insulin ratio) derangements, and elevated leptin (Morfeld and Brown, 2014b). Interestingly, ovarian cycle activity in Asian elephants seems to be less affected by obesity, despite the fact that over three-quarters are considered overweight.

Reproductive tract pathologies

As reviewed by Hildebrandt *et al.* (2006), older nulliparous females, or those that have not calved within ~10 years often develop urogenital tract pathologies. The most common are cysts and tumors, with some species differences. Endometrial hyperplasia and vestibular cysts are found in both species, whereas uterine leiomyomas are present only in Asian, and vestibular polyps are observed only in African elephants. Vaginal cysts and neoplastic formations may be extensive and fill the lumen, blocking semen flow and causing discomfort during estrus and mating. These pathologies may be a consequence of continuous ovarian cyclicity and hormone exposure in non-bred females. In the wild, most elephants are either pregnant or lactating and thus experience comparatively few reproductive cycles in their lifetime. Consequently, rates of urogenital tract pathologies are higher in captive elephants (20–80% in Asians and 10–33% in Africans), and relatively rare in wild elephants (<5%). Use of GnRH vaccines to inhibit pituitary FSH and LH release reduces ovarian steroidogenic activity, and have been effective in resolving uterine cysts and tumors in older Asian elephants (Boedeker *et al.*, 2012).

Male Reproduction

General Reproductive Biology

Similar to females, there is a shift in the onset of sexual maturity between captive and wild elephant bulls, particularly for Asians. Successful matings have occurred in captive males as young as 6 years of age, whereas wild bulls generally do not breed until they are

25 years of age or older. Elephant society is matriarchal, and bulls generally are ousted from the herd at puberty. A misconception is that bull elephants are solitary in the wild, when in fact they often travel in small, bachelor groups in search of estrous females. Both captive and wild bulls form social hierarchies that are influenced by age, size, and musth status.

Anatomy

There are a number of notable anatomical differences between elephants and other terrestrial mammals, in part related to the intra-abdominal testes (Short *et al.*, 1967; Hildebrandt *et al.*, 1998, 2000; Fig. 6). These hang from the dorsal wall of the abdominal cavity medial to the kidneys, and can weigh up to 2 kg each. The bull elephant has no inguinal canal, cremaster muscle, or

(a)

pampiniform plexus. The efferent ducts are highly convoluted and radiate dorsally from the extragonadal rete testis on the anterior aspects of the testes. The epithelial lining the efferent ducts is a low pseudo-stratified columnar type composed of ciliated and stereociliated cells and some basal and halo cells. The epididymis runs posteriorly along the testis within the mesenteric fold, and is comparatively less developed than that of scrotal mammals. Structurally, it can be divided into proximal, isthmus and distal regions, although these are not as distinct as those in other mammals. The epididymis is lined by pseudostratified stereociliated, columnar epithelium composed primarily of principal and basal cells. Motile sperm are present in the distal epididymis, but most sperm storage occurs in cone-shaped ampullae, widened terminal portions of the vas deferens and large glandular structures that open into the ducts of the corresponding seminal vesicles. The prostate glands are lobulated and located on the dorsal wall of the urethra, immediately posterior to the seminal vesicles. In Asian elephants, the three lobes of the prostate fuse into a globe-shaped structure, whereas in the African elephant there are clearly distinguished lobes with separate, irregularly shaped internal cavities. The seminal vesicles are the largest accessory glands, characterized by a single cavity, and produce a fructose-rich fluid. Paired bulbourethral glands are located directly below the anus on both sides of the urethra and penis, and produce a clear, sticky secretion containing sialic and citric acids. The penis is muscular and vascularized, about 1.5–2 m in length, and weighs up to 27 kg. It has a well-defined corpus cavernosum and large paired muscles on the dorsal side that allow for considerable voluntary control during mating. The shape of the penis is sigmoidal when erect, which facilitates entry into the vestibule that opens between the hind legs of the female.

Semen Characteristics and Cryopreservation

Semen can be collected by electroejaculation, artificial vagina or rectal manual message. Determining ampullae fullness by transrectal ultrasound indicates the probability of successful collection. Ejaculates normally range between 50–200 mL in volume, and are white in color, although yellow, orange and brown color variants occur. Low motility, sometimes accompanied by agglutination, is observed in many semen samples, often in samples contaminated with urine during the collection process (Schmitt and Hildebrandt, 1998; Kiso *et al.*, 2011). In Asian elephants, lactotransferrin, a potential fertility marker in human semen (Milardi *et al.*, 2012), has been shown to be abundant in ejaculates with good motility, and primarily absent in those with poor motility (Kiso *et al.*, 2013). Semen stored at 35°C exhibits a rapid decline in motility after a few hours in both species, whereas spermatozoa held at 22°C and 4°C can maintain at least partial motility for 12–24 h (Kiso *et al.*, 2011; O'Brien *et al.*, 2013). DNA damage and morphological degeneration is a contributor to poor semen quality (Imrat *et al.*, 2012; O'Brien *et al.*, 2013). Asian elephant spermatozoa appear to be particularly susceptible to DNA damage, more so than that of African elephants and other mammalian species (Imrat *et al.*, 2012). Addition of semen extenders increases spermatozoal longevity at chilled temperatures, with some species differences: for example, Asian elephant spermatozoa are best maintained in extenders containing egg yolk or skim milk, whereas spermatozoa from African elephants have no such requirement (Graham *et al.*, 2004; Saragusty *et al.*, 2005; Hermes *et al.*, 2009; Saragusty *et al.*, 2009; Kiso *et al.*, 2011). Cryoprotectants (i.e., dimethyl sulfoxide, glycerol, ethylene glycol and propylene glycol) added before cooling and freezing enhance cryosurvival, with glycerol appearing to be the most effective (Thongtip *et al.* 2004; Saragusty *et al.* 2009; Buranaamnuay *et al.*, 2013). For cryopreservation, most extenders for elephant semen cryopreservation contain a minimum of 15–20% egg yolk (Graham *et al.*, 2004).

Musth

In both species, musth is a period of heightened aggressive and sexual behavior associated with temporal gland secretions (TGS), urine dribbling (UD) and elevated androgen (e.g., testosterone, dihydrotestosterone, androstenedione) production (Jainudeen *et al.*, 1971, 1972; Ganswindt *et al.*, 2002, 2005; Brown *et al.*, 2007). It has been compared to rut in other ungulates; however, unlike rut, musth is not strictly seasonal. Wild bulls generally exhibit musth once a year, which can last a few weeks to several months, and is related to age, nutrition, and social status (Jainudeen *et al.*, 1972; Cooper *et al.*, 1990; Lincoln and Ratnasooriya, 1996). Testosterone concentrations increase 10- to 50-fold during musth compared to non-musth. In the wild, musth occurs in sexually mature bulls, generally those over 25 years of age. However, in captivity, musth signs have been observed in bulls as young as 7 years old (Cooper *et al.*, 1990). In many zoo elephants, musth-like changes often are irregular and can occur several times a year (Brown *et al.*, 2007). These patterns may not reflect true musth, however, because they often are not accompanied by UD. By definition, musth refers to the competitive state in sexually active male elephants, with the presence of UD being a defining physical signal (Ganswindt *et al.*, 2005). Analogous to females, captive African bulls appear to mature slower than Asian males based on hormonal analyses and musth signs (Brown *et al.*, 2007).

Bull elephants advertise their musth status through a variety of chemicals exuded in TGS and urine. In young Asian bulls <15 years of age, TGS consists of sweet odors: acetates, an alcohol (3-hexen-2-ol) that smells of leaves, and pleasant smelling ketones (acetophenone and 2-heptanone) (Rasmussen *et al.*, 2002; Riddle *et al.*, 2006). This is referred to as honey or moda musth, and is associated with behaviors that are more erratic and unpredictable. It also is of a shorter duration and associated with comparatively lower androgen levels. Moda musth has not been described for juvenile African elephant bulls, however, which may reflect a species difference. In Asian elephants, the compounds of moda musth are transitionally replaced by more malodorous compounds, like carboxylic acids, and a chemical signal found in insects – frontalin. In older Asian and African elephant bulls, musth urine contains higher levels of alkan-2-ones, alkan- 2-ols, and some aromatic compounds compared to urine of females and non-musth males (Riddle *et al.*, 2006; Goodwin *et al.*, 2012). Elephants have well-developed primary and secondary (vomeronasal) olfactory systems

(Lazar *et al.*, 2004), and both males and females respond to these chemicals. Estrous females seek out musth bulls, while sub-adult and non-musth males exhibit avoidance behavior when exposed to musth semiochemicals (Riddle *et al.*, 2006; Goodwin *et al.*, 2012). Ultimately, the state of musth confers an advantage to adult bulls, which gain more access to estrous females and experience a higher paternity success (Hollister-Smith *et al.*, 2007).

Function of the hypothalamo-pituitary-testicular axis in elephants appears to be similar to that in other species. Pulses of testosterone closely follow those of LH (~1 pulse/3 h), and GnRH administration results in LH-stimulated testosterone release (Niemuller and Liptrap, 1991; Brown *et al.*, 1993). There is little difference in LH pulse rate between musth and non-musth Asian bulls; however, testosterone patterns indicate testes become hyper responsive to LH, both pulsatile and GnRH-induced, during musth (Brown *et al.*, 1993; Lincoln and Ratnasooriya, 1996). Increased numbers of LH receptors in testicular tissue of musth bulls are related to this hyper testosterone secretion.

A schematic of hormonal relationships associated with musth is presented in Fig. 7). Circulating cortisol increases during musth, at least in captive bulls, and is positively correlated with serum testosterone (Brown *et al.*, 2007; Yon *et al.*, 2007). Serum gonadotropin patterns are not always consistent, but in many bulls, LH is elevated for several weeks about a month before musth begins, while FSH concentrations are higher during the pre-musth period and decline during musth (Kaewmanee *et al.*, 2011b). FSH in elephant bulls is inversely related to inhibin, which in turn correlates positively with testosterone (Kaewmanee *et al.*, 2011b). In other species, and presumably elephants, inhibin is produced by Sertoli cells in response to FSH, which then controls pituitary FSH secretion through a negative feedback loop. Another hormone produced by Sertoli cells under FSH control is AMH, which can be used as a marker of FSH and testicular function. AMH is higher in pre- versus postpubertal elephant bulls; however, there are no differences in concentrations between musth and nonmusth males (Dow *et al.*, 2011b). AMH concentrations are higher than in female elephants (over 100-fold), regardless of age or gonadal status, which has been found other species.

Due to the dangers associated with managing bulls, there is considerable interest in finding treatments to mitigate musth behaviors. Castration is not a practical option given the abdominal location of the testes, although it has been done. Musth is affected by nutritional status, so a common management strategy is to reduce water and food. Musth bulls also are often isolated, and in Asia they are kept on short chains away from other elephants and people. Both of these strategies raise animal welfare concerns, so alternative therapies that decrease androgen secretion or action are being sought. GnRH agonists, like leuprolide acetate, can reduce testosterone during musth, but need regular injections (Brown *et al.*, 1993; de Oliveira *et al.*, 2004). Cyproterone acetate (an antiandrogen) has been given to Asian elephants, but with little effect on aggressive behaviors (Niemuller *et al.*, 1998). More recently, GnRH vaccines have shown promise as a means to reduce testosterone production (De Nys *et al.*, 2010; Somgird *et al.*, 2016). Not all bulls respond with a reduction in musth symptoms, however, which may be a learned behavior. Long-term treatment with GnRH vaccines also can result in permanent immune-castration, so should be used cautiously (Lueders *et al.*, 2014).

Assisted Reproduction

One of the most significant advances in elephant reproductive management has been the development of an artificial insemination (AI) technique in the 1990s (Hildebrandt *et al.*, 1999; Brown *et al.*, 2004b; Thongtip *et al.*, 2009). The non-surgical procedure involves a custom-made balloon catheter (2.5-cm diameter 140 cm length), lubricated with nonspermicidal sterile gel, inserted into the vestibule to slightly distend the tract for optimal visualization and to allow passage of a flexible 3.0-m endoscope containing a disposable semen catheter. Both endoscopic and transrectal ultrasonographic visualizations are used to guide the insemination catheter to the distal vagina in front of the cervical opening or intracervically; proper semen deposition is then confirmed ultrasonographically. The timing of AI is based on identifying LH1 in daily blood samples during the follicular phase of the cycle, and then conducting 2–3 inseminations ~18–21 days later to coincide with LH2. Monitoring LH in elephants is only possible with blood serum or plasma, as no immunoreactivity has been detected in urine (Brown *et al.*, 2010). The first elephant AI birth was in 1999; since then >50 births have resulted worldwide. Continuing challenges in the successful use of AI in elephants include: (1) the inability to consistently obtain good quality ejaculates; (2) poor spermatozoa survival after liquid storage and transport; and (3) low post-thaw motility of cryopreserved sperm. Calves have been produced successfully by AI using cryopreserved sperm in African elephants, including with imported frozen semen from a wild African bull (Hildebrandt *et al.*, 2012b). However, most AIs are done using fresh or chilled semen, which limits AI effectiveness if good quality ejaculates are not collected on peak fertility days. Thus, while AI is clearly an important management tool for breeding elephants, maximal impact will not be achieved until good quality samples can be reliably collected and cryopreserved.

The benefit of AI also would be greatly enhanced by the ability to preferentially produce female offspring using sex-sorted semen (Johnson *et al.*, 1987). As more zoos become involved in breeding elephants by both AI and natural mating, the number of males will continue to increase. A high proportion of male elephants in captive collections is not needed for sustainability nor is it desired. The successful separation of elephant sperm based on the DNA difference between X and Y chromosomes using flow cytometric methods suggests this is a possibility (Hermes *et al.*, 2009). Ultimately the goal is to establish genome resource banks for elephants, which if they include sex-sorted cryopreserved sperm from captive and wild bulls, would greatly enhance the genetic management of elephants under human care.

Conservation and Management

Through advances in reproductive monitoring, and the ability to collect longitudinal biological data, many unique aspects of elephant biology have been identified, and today the two species are considered relatively well-studied compared to many other wildlife. The knowledge gained has contributed to improved management of *ex situ* elephants, and a better understanding of factors affecting the survival of elephants *in situ*. Today, extensive conservation efforts are underway to protect the remaining wild elephant populations, with varied success. African elephants are declining at an alarming rate, around 8% annually, mostly due to poaching. There are <400,000 wild African elephants today, down from several million in the early 20th century. Asian elephants are even more endangered, with <50,000 distributed across 13 range countries. Population declines in Asia are due not only to poaching, but to deforestation, habitat loss, population fragmentation, and human-elephant conflict. Many Asian range states now have <1000 elephants left in the wild, often fragmented, and so those populations may not be sustainable in the long term. In captivity, there are perhaps 1500 African elephants held in zoological collections, whereas there are as many as 15,000 Asian elephants currently used for tourism, logging, religious activities and poaching patrols. Unfortunately, because of poor breeding success, replenishment of captive stocks has involved capturing of wild elephants, which further depletes fragile populations and raises ethical and welfare concerns. In Asia, wild capture is now banned, although not always enforced.

We need to understand why reproductive rates are low in many elephant populations under human care, and develop ways to mitigate roadblocks to achieving reproductive success and sustainability. New approaches for managing social groups, meeting nutritional needs, improving enrichment and exercise regimens, and finding ways to promote normal behaviors might avoid some of the problems associated with cohort incompatibility, asymmetric reproductive aging, gonadal dysfunction and poor pregnancy outcomes. It is unlikely that any one factor is responsible, especially given the diversity of ways elephants are managed worldwide, so it will be key to ascertain if problems are of physical or behavioral origin, and identify the best approaches to ameliorate them. Ironically, left alone, elephants reproduce well in the wild – so much so that in some highly-protected areas, population control methods, such as culling or immuno-contraception (e.g., GnRH or porcine zona pellucida vaccines), are necessary.

Last, while elephant conservation has centered on saving habitat and, by extension, the species therein, the magnitude of population declines now means that all options must be considered, including management of captive collections in zoos, breeding centers, and sanctuaries. Today, many wild elephant populations are intensively managed and protected, so in a sense they also are ‘under human care,’ just on a much larger scale. Ultimately, the long-term preservation of elephants will depend on the use of a wide range of tools, low and high tech, often modified from traditional animal models and adapted to meet species-specific needs.

Snakes

Introduction

Snakes are amniotic vertebrates with internal fertilization and genetic sex determination that share much in common with other amniotes with regard to reproductive anatomy, physiology, behaviour and life history. However, numerous distinctive features of snakes, including a limbless, elongate body form, secretive lifestyle, diversity in reproductive modes, ectothermy, indeterminate growth, diverse life-history strategies and flexible responses to environmental variables make them an excellent model for the study of reproduction, in mechanistic, ecological, and evolutionary dimensions.

Basic Reproductive Anatomy

Like other reptiles, male snakes have paired testes which are housed internally (**Fig. 1(A)**). Testes are displaced within the narrow body cavity, with the right testes more anterior than the left, so as to prevent overlap. Sperm is released via paired hemipenes, male intromittent organs present in all squamate reptiles (i.e., snakes and lizards). Hemipenes are maintained in an inverted position at the anterior end of the tail (**Fig. 1(B)**), but are everted from the vent (cloaca) during copulation. A single hemipene is inserted into the female, but males may alternate left and right hemipenes during subsequent matings. Male snake also have region of the kidney called the sexual segment of the kidney, which is involved in the production of copulatory plugs (discussed below).

Female snakes have paired ovaries, also displaced from one another, with follicles from each ovary arranged in a roughly linear fashion (**Fig. 2(A)**). After vitellogenesis, eggs are ovulated into a single oviduct prior to fertilization. Within the oviduct, eggs tend to be arranged in a linear sequence (**Fig. 2(B)**), filling the maternal abdomen from just below the gall bladder to just above the vent, though overlap among eggs may occur, especially in large snakes. Both oviparity and viviparity are broadly distributed across the snake phylogeny ([Seigel and Ford, 1987](#)). Developing embryos in oviparous species rely primarily on nutrient stores within yolk deposited during vitellogenesis. Developing embryos in viviparous species (**Fig. 2(C)**) will also primarily rely on yolk for nutrients, but can additionally derive some level of nutrients and/or water via placental connection with their mother ([Stahlschmidt and DeNardo, 2011](#)).

Reproductive Cycles

Annual timing of reproduction is a critical ecological decision that should minimize the costs to breeders and maximize the chances of offspring success in a given environment. The most basic requirement is that both sexes must be reproductively active at the same time for fertilization to occur. Furthermore, environmental temperature must be at a level that allows the movement required to find mates and avoid predators during courtship and mating activities ([Krohmer and Lutterschmidt, 2011](#)). Offspring development and hatching/birth should also occur under favorable thermal conditions, and the stage of juvenile development at which individuals are prepared to forage independently should coincide with peaks in resource availability. Natural selection favors responsiveness to environmental cues that help maximize reproductive success given different environmental challenges. Across vertebrates,

Fig. 1 Ultrasound images of male sexorgans in common kingsnakes from southern California. (A) The right testes. (B) Paired hemipenes (small arrow indicates location of vent.).

Fig. 2 Ultrasound images of the abdominal cavity of viviparous female common garter snakes from northern California. (A) Inactive ovary; arrows indicate individual follicles. (B) Two postovulatory eggs, with A/B arrows demonstrating the full dimensions of a single egg. (C) Three late-stage embryos, with little yolk remaining, and the skull and coiled thoracic vertebrae of the middle embryo clearly evident.

environmental cues for the commencement of reproductive activity include changes in photoperiod, temperature, rainfall, resource availability, and social activity.

Evidence suggests that environmental temperature is a major cue for the commencement of the breeding season for snakes in temperate regions, where seasonal changes in temperature and resource availability are pronounced. This may be a consequence of the fact that snakes living in these regions may overwinter underground in hibernacula, where other cues such as photoperiod and rainfall may not penetrate, but surface warming can result in detectable changes in ground temperature (Krohmer and Lutterschmidt, 2011). In tropical regions, where temperatures can remain high year-round, environmental cues for breeding are less well understood. In these areas, reproductive schedules may be more determined by cycles in predators that prey on eggs or hatchlings, or by cycles of resource availability. There is also evidence that reproductive schedules in tropical snakes may be timed to coincide with annual reductions in rainfall, which reduces the danger of eggs becoming waterlogged (Brown and Shine, 2006). In both temperate and tropical regions, snakes can also respond to more immediate cues, such as pheromones from receptive females (discussed below), that trigger mating behaviour.

General trends in reproductive cycles for both males and females have been most clearly elucidated for temperate species (Seigel and Ford, 1987; Fig. 3). Spermatogenesis in temperate regions has been categorized into two general patterns: prenuptial and

Fig. 3 A general timeline for annual reproductive events in temperate snakes.

postnuptial. Prenuptial spermatogenesis (also called the associated pattern of reproduction) is the more intuitive and widespread pattern, where sex steroids and testicular activity peak in the spring in preparation for spring mating. In contrast, for postnuptial spermatogenesis (also called the dissociated pattern of reproduction), the peak in sex steroids and testicular activity occurs in late summer and early fall, and sperm produced during this time is stored over the winter months, to be used during breeding the following spring.

In temperate regions, timing of vitellogenesis may also occur pre- or post-nuptially. For prenuptial vitellogenesis, most follicular growth occurs in the spring immediately prior to mating. Postnuptial vitellogenesis, in contrast, begins at the end of summer, and is completed post-hibernation. In some species, mating can also occur in the fall, and sperm is stored by the female in the oviduct over the winter months. Ovulation and fertilization generally occur mid to late spring, oviposition at the beginning of summer, and hatching/birth in late summer and early fall. Many species may undergo vitellogenesis and ovulation within the same year, though some species may take years for eggs to reach ovulation. Mating typically occurs after ovulation, and fertilization occurs in the oviduct; however, there is evidence that in some species, mating itself may induce ovulation (Seigel and Ford, 1987).

The vast majority of snakes in both temperate and tropical regions exhibit seasonal reproductive cycles, though reproduction may be more asynchronous among individuals and occur over a more extended season in tropical species. Even so, there is some evidence that spermatogenesis can occur continuously in some tropical species, even when mating is seasonal (Mathies, 2011). However, in spite of numerous studies in the past few decades, particularly in South America and Australia, reproductive cycles of tropical snakes have been difficult to elucidate. This is likely due to the fact that individual cycles are less synchronous and patterns in individual cycles are still largely unknown, making general population and species-specific patterns more difficult to dissect.

Courtship and Mating

Only one snake, the flowerpot snake is known to be entirely parthenogenetic and reproduce clonally (Gillingham, 1987). While facultative parthenogenesis (involving occasional clonal reproduction by unmated females) has been reported in diverse snake clades, the vast majority of snake species reproduce sexually (Booth and Schuett, 2016). Thus a major component of reproduction in snakes is locating a mate and successfully initiating copulation. Snakes in high latitudes can hibernate in large aggregations and are able to engage in courtship activities almost immediately after emergence. In many species, however, it is more of a challenge to locate a mate, especially when population density is low, as snakes do not vocalize, and visual signals are effective only over short distances.

One potential means for males to locate females is via pheromone trails deposited by females as they move across the landscape (Parker and Mason, 2011). Pheromones are chemicals that can provide information-bearing signals to receivers. In snakes, pheromones can be detected via tongue-flicking, which collects pheromones from a substrate and delivers them to the vomeronasal organ in the roof of the mouth. Experimental studies show that males can recognize the direction of female movement given a pheromone trail. The extent to which pheromone trailing is used in the wild is unknown; however, when it occurs, it is likely complex, especially when numerous males are trailing a single female, disrupting her pheromone trail.

Whatever the means, the ability to locate females is likely a major factor in reproductive success, particularly when females are sparsely distributed. Body size also appears to be an important factor, with larger males in some species tending to obtain more matings. In European adders, for instance, the ability of larger males to obtain more matings may be due at least in part to an advantage during ritualized male-male combat (Madsen *et al.*, 1993). Smaller male adders, however, may employ alternative mating tactics, avoiding combat altogether and achieving some success in mating with females as they are leaving the territories of larger males.

Unlike other terrestrial vertebrates, snake courtship is primarily a tactile and chemosensory affair, with limited visual and auditory components. Their elongated, limbless morphology allows a high level of body contact between mating individuals. With the exception of some species that mate regularly in highly visible aggregations, reports of snake mating behaviour in the wild are largely anecdotal in nature, with a limited number of mating events completely described for any given species. However, there is enough information to suggest that courtship can be classified into three general phases: (1) tactile-chase, (2) tactile-alignment, and (3) intromission and coitus (Gillingham, 1987).

The tactile-chase phase (1) involves initial contact and preliminary courtship. During this period, males tongue-flick rapidly, evaluating pheromones from the female's skin that can encode information about species, body condition, and reproductive status. During this time males may also make visual assessments of females, and evidence suggests that males tend to prefer larger females. Since body size and body condition can be strongly positively correlated to fecundity, this suggests that both of these visual and chemosensory signals may act as honest signals of female quality. Interestingly, however, male common garter snakes can also produce "female" pheromones upon emergence from communal hibernacula (Shine, 2003). These so-called "she-males" can induce other males in large snake aggregations to attempt to mate with them. This form of female mimicry is currently thought to attract other males that can confer thermoregulatory advantages for cold snakes that are just emerging, by allowing heat transfer between individuals and reducing exposure. Furthermore, attracting other males may help shield female mimics from predators, which can be numerous at den sites. Since species such as this form mating balls that may involve numerous males attempting to mate with a putative female, both thermoregulatory and antipredator benefits could be substantial. Whatever the case, this appears to be a short-term strategy, as female pheromones tend to dissipate from males soon after they emerge, and males do show preference for true females over female mimics.

After preliminary contact, a male will attempt to mount the female. If the female flees, the male may pursue her and attempt to mount again. If mounting is successful, the male will engage in precopulatory behaviours such as chin rubbing on the female dorsum, undulation, caudocephalic and/or cephalocaudal waves (waves of contraction running from head to tail, or vice versa), tail whip, head shake, and courtship biting, with some clades more likely to exhibit certain behaviours than others. Male pythons or boas, for instance, use small vestigial hindlimbs called pelvic spurs to “spur” or stroke the female back. Chin-rubbing on the female’s dorsum and head/body jerking appears to have evolved ancestrally in the Colubroidea and is widespread throughout that clade (Senter *et al.*, 2014).

The tactile-alignment phase (2) begins with the first copulation attempt, and involves tail searching behaviour, wherein the male attempts to align his cloaca with that of the female. This is the most consistent courtship behaviour across taxa. If the search is successful, and female gaping of the cloaca occurs, there is hemipene intromission and coitus (3). Copulation time varies considerably among species, with some requiring only a few minutes, and others remaining joined for over 24 h. Short copulatory times are hypothesized to be favored due to heightened predation risk during mating; however, sexual selection may favour longer copulatory times in some species as it may allow a male to prevent competitors from mating with the same female.

There appears to be little direct post-mating interaction between males and females. In some species, particularly those that engage in male-male combat, males may occasionally guard females after mating. In other species, a male may leave the female with a gelatinous copulatory plug, which derives from secretions from the sexual segment of the kidney and is deposited during ejaculation. It was originally proposed that this plug primarily functioned as a form of mate guarding, effectively preventing mating by other males in the short-term. However, recent work suggests that this may not be the only (or a particularly effective) function of copulatory plugs, at least in common garter snakes (Friesen *et al.*, 2013). Rather, it may also prevent the sperm leakage and loss immediately after copulation and act as a spermatophore, slowly releasing sperm as the plug degrades. There is some evidence that male garter snakes may deposit an inhibitory pheromone into the female that reduces her receptivity and attractiveness to other males; however, controversy remains as to whether an antiaphrodisiac pheromone such as this exists, or whether female willingness to mate again is driven by other factors, such as cryptic female choice based on quantity and quality of sperm received from her previous mate (Friesen *et al.*, 2014).

Mating systems among snakes tend to be polygynandrous, with both males and females mating multiple times. Sperm from each mating is stored in sperm storage tubules within the female urogenital tract, and multiple paternity is widespread throughout the snake phylogeny (Jellen and Aldridge, 2011). There is some evidence that multiple paternity can increase female fitness. However, little is currently known regarding the dynamics of cryptic female choice in snakes, whereby a female’s reproductive tract gives fertilization preference to some sperm over others. Studies using molecular methods to investigate paternity dynamics in the wild suggest that in some cases sperm from larger males, or males that are last to mate may fertilize the most eggs; other work, however, shows no clear relationship between male body size and precedence and fertilization success (Clark *et al.*, 2014).

Parental Care

Parental care can be defined as any non-genetic contribution by a parent that increases the fitness of offspring, and can occur before or after laying or birth (Stahlschmidt and DeNardo, 2011). In snakes, females are the primary parents providing care for offspring. Female energetic investment and thermoregulatory choices constitute most basic forms of prenatal parental care. On an energetic level, this may include the quantity and type of fats and proteins deposited by a female into her eggs during vitellogenesis. Female snakes are also known to transfer minerals, immunoglobins, antioxidants, and defensive toxins into their eggs, though the adaptive significance of such provisioning is still unclear. The amount of investment in eggs can contribute to individual differences in growth rate and offspring survival.

Behavioral thermoregulation by females is another critical component of prenatal parental care, wherein gravid females alternately bask and seek shade to modulate their body temperature, sometimes in aggregations with other gravid females. Even oviparous squamates may complete at least a quarter of embryonic development prior to oviposition, such that embryos in both oviparous and viviparous species are dependent on maternal thermoregulatory behaviour for optimal developmental conditions. In fact, one of the major hypotheses for the evolution of viviparity in squamates, the Cold Climate Hypothesis, suggests that viviparity has evolved primarily in cold climates due to increased maternal control of temperature in developing embryos (Stahlschmidt and DeNardo, 2011). Viviparous females can also be involved in hydoregulation of embryos during development, transferring water via placental connection. A more generalized hypothesis for the evolution of viviparity, the Maternal Manipulation Hypothesis, suggests that females retain embryos in order to better protect them from a range of ecological challenges, ranging from excessive temperatures to dehydration risk to predation. Recent work suggests that the evolution of viviparity itself may have introduced novel selective pressures on embryos competing for water within their mother’s body, particularly in arid or marine environments where fresh water is limited (Bonnet *et al.*, 2017).

For oviparous species, nest-site selection is an important facet of parental care. Snakes commonly oviposit in areas such as rock crevices, rodent burrows, and rotting logs. In some cases, female may excavate sites with soft substrate. Some may choose sites with eggshell remnants indicating successful incubation in the past, and/or return to a site where they themselves have previously nested. Females must select nest sites in areas with appropriate magnitude and variability in environmental temperature for embryonic development within the egg, and appropriate levels of humidity and substrate water content (neither too dry nor too wet) to aid in hydoregulation. Another critical factor in nest-site selection is minimization of predation risk, as a variety of predators,

ranging from birds to other snakes, can pose a risk to egg survival. Some species are well known to nest communally. Though the significance of such behaviour is unknown, potential explanations range from defense from predators, to thermoregulatory and hydoregulatory benefits of clustering, to hatching synchrony via communication among embryos. Recent experimental research in water snakes suggests that embryos incubated without contact with siblings are generally less sociable after birth, indicating that there may be communication, possibly via heartbeats or odours, among eggs laid in the same nest that influences social bonding (Aubret *et al.*, 2016).

Parental care after birth or oviposition has been documented only occasionally or not at all in most snake families. Reports generally involve females remaining with eggs or neonates. Benefits of maternal attendance could involve thermoregulation, hydoregulation, active defense from nest predators, and/or cryptic colouration of the mother concealing white eggs from predators. At this point, it is unclear whether reports of this type of parental care are sporadic because they are uncommon, or because snakes tend to be secretive, allowing limited opportunities for observation of their interactions with offspring. That said, postnatal care has been well-documented in two major clades: pit vipers and pythons (Stahlschmidt and DeNardo, 2011). In temperate pit vipers, such as rattlesnakes, neonate attendance is widespread, and generally lasts until the first shedding (ecdysis) of neonates. In pythons, egg attendance may involve the female coiling around her clutch and engaging in shivering thermogenesis, generating heat to warm the eggs. Coiling around eggs may also prevent both heat and water loss.

Life History Variation

Snakes exhibit remarkable diversity in life-history traits, ranging from age and size at maturity, to reproductive lifespan, to size and quantity of young. For instance, while many snakes may have clutch sizes ranging from two to two dozen, there are reports of individuals of some species having clutch sizes of over 50, or even more than 100 offspring. One of the major factors affecting life history variation is maternal body size, with larger females tending to have more offspring due to a greater capacity within the abdominal cavity to accommodate eggs. Larger females also tend to have larger offspring, though this relationship does not appear to be as strong (Seigel and Ford, 1987).

The relationship between maternal size and clutch size is not perfect, as number of offspring may also be related to phylogenetic constraints (i.e., the constraints on reproduction within a particular lineage), size of individual offspring, and ecological context. Size of offspring may trade off with number for any given amount of energy available for reproduction, resulting in a choice of whether to make a few large young or many small (Seigel and Ford, 1987). Furthermore, the ecological context, which includes factors such as availability of prey and predation risk, can generate both plastic (i.e., environmentally induced) and genetic variation in life-history strategy.

Intraspecific geographic variation in life-history strategy among snakes has been described across latitudinal and altitudinal gradients, between island and mainland populations, as well as across habitat types within the same region. Well-characterized populations of western terrestrial garter snake in California, United States, provide a prime example of geographic variation in life-history strategy across habitat types (Bronikowski and Arnold, 1999). These populations are distributed across two major habitat types within the same vicinity: the rocky lakeshore of a large natural lake, and nearby grassy montane meadows. Differences among habitats are thought to be major factors in the evolution of two distinct life-history ecotypes. Lakeshore snakes exhibit rapid growth to large body sizes, early maturation, large litters, and short lifespan, whereas meadow snakes exhibit slow growth to smaller body sizes, delayed maturation, small litters, but more extended lifespans (Table 1). Evidence suggests that higher resource availability as well as higher predation pressure have selected for a faster life-history strategy in lakeshore populations, which may have generated a trade-off between fast growth/high reproduction and lifespan, as theory would predict. Interestingly, while classic life-history theory predicts that fast-living organisms should age more rapidly, lakeshore snakes do not show evidence of faster reproductive senescence than meadow snakes (Sparkman *et al.*, 2007). Rather, lakeshore snakes continue to increase their reproductive output as they get older and larger. This indeterminate growth has been proposed as a means of evading some of the trade-offs expected in determinately growing species. Though the two ecotypes differ according to a variety of physiological metrics, such as metabolic rate, DNA damage and repair, innate immunity, and corticosterone levels, the physiological mechanisms underlying differences in reproduction per se between the two habitat types have not been fully elucidated (Schwartz and Bronikowski, 2011). However, there is some evidence that ecotype-differences in circulating insulin-like growth factor-1 in the wild may be related to differences in litter size.

Table 1 Differences in body size (snout-vent length) and reproductive variables between two garter snake life-history ecotypes residing in meadow and lakeshore habitats in the vicinity of Eagle Lake, California, United States

	<i>Meadow ecotype</i>	<i>Lakeshore ecotype</i>
Mean adult body size	538 mm (range: 370–598)	660 mm (range: 395–876)
Female maturation size/age	400 mm/5–7 years	425 mm/3 years
Reproductive rate	Biennial or even less frequent	Annual
Mean litter size	4.3 (range: 1–6)	8.8 (range: 1–21)
Newborn mass	2.85 g (range: 1.8–3.5 g)	3.27 g (range: 2.5–4.2 g)

In general, reproductive life history in snakes, as in other species, is a negotiation between the fitness costs and benefits involved in any given reproductive event. In snakes, costs to gravid or pregnant females include not only the energetic costs of egg production, but also reduced mobility and increased predation risk. Furthermore, frequency of reproduction in snakes can be a function of both past and current resource availability, with some species relying more on energetic stores from the previous years (capital breeders), and others relying more on current foraging (income breeders). In contrast to lizards and turtles, which commonly reproduce annually with multiple clutches, snake species in temperate regions appear to be restricted to a single litter or clutch per year in the wild, likely due to both seasonal and energetic constraints. However, there have been some recent reports of multiple clutches per year in tropical species (Mathies, 2011). Furthermore, frequency of reproduction across years may differ phylogenetically and geographically, or even among individuals within a population, with females breeding every year in some cases, or every other year (or even less frequently) in others.

Conclusion

While much valuable knowledge has been gained thus far regarding the physiological, ecological, and evolutionary dynamics of reproduction in snakes, much remains to be learned. Studies have become increasingly sophisticated over recent years, but the use of advanced techniques, such as molecular methods for studying mating systems and sexual selection, has only just begun. Similarly, ultrasonography has yet to be used to its full potential to discern patterns and test hypotheses on topics ranging from the physiology of maternal-fetal interactions to phenological changes in development in response to global climate change. Furthermore, as technologies to track and monitor individuals in the wild continue to advance, and more long-term studies are conducted in a broader array of species, much-needed data on factors involved in annual cycling, mate choice, nesting, parental care, and reproductive effort will continue to fill in our understanding of the ways in which reproductive physiology, behaviour and life history vary within and across species, and across ecological contexts.

Reproduction in Nonhuman Primates

David H Abbott, University of Wisconsin, Madison, WI, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Today, almost 400 species of nonhuman primates live across five continents in forests, savannas, grasslands, semi-deserts, snowy mountains and even cosmopolitan cities. While some are mostly solitary, many are social, ranging from breeding pairs and small family groups to large gregarious troops comprising multiple breeding males and females and their offspring. “The nonhuman primate” is therefore a misnomer, even though the term is widely used, and usually means a select few species of macaques and baboons (Strier, 1994). Nonhuman primate diversity is rich, highly evolved and comprises five “natural groups”: Malagasy (Madagascar) lemurs, the loris group, tarsiers, New World monkeys (NWP), and most well-known, Old World monkeys, apes and humans (OWP) (Martin, 2007). NWP and OWP are collectively known as anthropoid primates. Most nonhuman primates live in the tropics and sub-tropics, so seasonality in breeding is regulated by reliable changes in climate, such as dry or rainy seasons, e.g., New World cotton top tamarins (*Saguinus oedipus*), in contrast to those in more temperate climes in which seasonal breeding is regulated by changes in day length, e.g. Old World Japanese macaques (*Macaca fuscata*) or “snow monkeys”. These five “natural groups” nicely delineate female reproductive differences, while in contrast, different types of mating systems better delineate male differences (Table 1).

So, how to address diverse nonhuman primate reproductive variation? We will examine selected aspects of reproductive biology for both males and females, illustrating reproductive specialization together with how sex-typical characteristics differ. In doing so, it will become clear how much we know about reproductive biology in a few, biomedically relevant nonhuman species, and how little we know about reproduction in most others. This skew in knowledge is becoming more pronounced as we realize the potential for genetic engineering of nonhuman primate oocytes, spermatozoa, and even mature adult somatic cells, as the bases for eradicating genetically-based diseases in ourselves (Sasaki, 2015).

Table 1 Distinct aspects of nonhuman primate reproduction

Males

- Permanent descent of the testes into a scrotum behind the base of the penis, typically around the time of birth
- In certain species, investment in individual offspring is considerable partly because age at sexual maturity is attained relatively late
- Multi-male and dispersed, small group mating systems: notable sexual dimorphism, relatively large testis size, voluminous ejaculates with high concentrations of sperm containing large, mitochondria-containing midpiece, complex penile morphology, multiple or prolonged intromissions prior to ejaculation, multiple ejaculations in relatively short period of time do not deplete sperm concentrations
- Single male and female mating systems: less extreme sexual dimorphism, less frequent and shorter duration, single intromission prior to ejaculation, multiple ejaculations in relatively short period of time deplete sperm concentrations

Females

- Complete separation of urinary and reproductive tracts
- Give birth to well-developed (precocial) neonates after comparatively long gestation
- Most species have just a single infant at a time
- Considerable investment in individual offspring, partly because age at sexual maturity is attained relatively late
- Placentation of lemurs and lorises is non-invasive, epitheliochorial
- Placentation of tarsiers, New and Old World primates is invasive, haemochorial
- Embryonic chorionic gonadotropin (CG) provides pregnancy recognition signal in New and Old World primates
- Estrous cycles: lemurs, lorises, tarsiers
- Ovarian cycles: certain New World primates
- Menstrual cycles: most New and all Old World primates

General

- Yolk-sac eliminated after mid-gestation
- Relative to body size, fetal and postnatal growth are slow
- Sexual maturity attained relatively late and life-spans are long
- New World primates exhibit transcriptional repression and decoy cytoplasmic binding with consequent elevation in circulating levels of steroid hormones
- New World primates replace pituitary LH with CG, and their LH/CG receptor only binds CG
- Old World primates retain pituitary LH and an LH/CG receptor that binds both LH and CG

New World Exceptionalism #1: Neuroendocrine Regulation

Typical of mammals and many vertebrates, nonhuman primate reproductive physiology is governed by the brain, in particular gonadotropin-releasing hormone (GnRH) producing neurons in the neuroendocrine hypothalamus. GnRH neurons migrate from the embryonic nose to the hypothalamus during early fetal life, and are triggered into action during puberty when they increase production and action-potential gated release of GnRH into surrounding extracellular fluid. Such synchronized bursts of GnRH release ensure rapid diffusion of high concentrations of the peptide into a network of tiny blood vessels flowing only to the anterior pituitary. At anterior pituitary gonadotrope cells, GnRH stimulates synthesis and release of the gonadotropins luteinizing hormone (LH) and follicle stimulating hormone (FSH) into the systemic circulation. NWP, however, differ from all other nonhuman primates and non-primate mammals, with regard to pituitary LH secretion and its action.

To put this neuroendocrine difference into perspective we need to appreciate primate phylogeny. From fossil, isotope and molecular dating, primates originated in the late Cretaceous about 80–90 million years ago. The lemur and loris lineages split off from those of the tarsiers and anthropoid primates by 65–70 million years ago. The first gene duplication of the *LHβ* gene into separate *CGβ* and *LHβ* genes occurred only in anthropoid primates, with molecular dating placing that event after the divergence of tarsiers from anthropoid primates about 45 million years ago (Maston and Ruvolo, 2002). Continental drift separated South America from Africa about 35 million years ago, thus preventing further influx of nonhuman primates to a now isolated, multi-island South America, causing the New and Old World split among anthropoid primates. Due to intense environmental selection pressure after continental separation, exaggerated expression of an otherwise rare variant of the 12-exon gene coding for primate LH/chorionic gonadotropin (CG) receptor type 1 (*LHCGR type 1*) occurred among NWP, alone. This genetic variant expresses an *LHCGR* that omits exon 10, designated *LHCGR type 2*, and binds CG, alone, and not LH. Not surprisingly in these circumstances NWP, unlike their OWP counterparts, retained pituitary gonadotrope transcriptional responsiveness to GnRH for the β subunit of CG, alone, instead of LH. OWP, in contrast, silenced pituitary transcription for the β subunit of CG (Troppmann et al., 2013).

Females in both anthropoid primate groups, however, retained CG expression in the embryonic trophoblast and fetal placenta as the “pregnancy recognition” signal to the mother. CG from the embryo binds to *LHCGR* on the maternal ovarian corpus luteum (CL), slowing the CL’s natural demise, preventing menses and prolonging the CL’s copious production of progestins, estrogens and relaxin required to support a nurturing uterine endometrial environment until the luteo-placental shift, when the maturing fetal placenta becomes self-sufficient in hormone production. NWP placentae employ a different gene promoter sequence for CG transcription than found in pituitary gonadotropes, reflecting differing transcriptional control for testis-ovary versus placental function. As clearance of CG from the circulation is prolonged in comparison to LH, episodic bursts of GnRH-stimulated CG release are relatively indistinct in terms of increased CG levels in the blood and so do not emulate LH reliability as a peripheral biomarker for frequency and amplitude of GnRH release. CG action in NWP, nevertheless, closely emulates that of LH in terms of stimulating testicular and ovarian function.

New World Exceptionalism #2: Steroid Hormone Synthesis and Action

Circulating levels of NWP steroid hormones, including testicular and ovarian progestins, estrogens and androgens, are commonly 5–10 times those found in OWP and other nonhuman primates, again reflecting NWP adaptation to environmental selection pressure following continental drift separation from OWP about 35 million years ago. Exaggerated expression of intra-cellular chaperone molecules diminish steroid hormone-mediated transcriptional action, and at least for progesterone (P_4), compensatory consequences led to the silencing of liver production of the circulating steroid hormone binding protein, cortisol-binding globulin (CBG), resulting in ~100% unbound and bioavailable circulating P_4 . Testosterone (T) and estradiol (E_2) prove exceptions to absent circulating binding globulin, since sex hormone binding globulin (SHBG) remains expressed, enabling anthropoid-typical bioavailability of unbound androgens and estrogens at usually <5% of total circulating concentration for each hormone (Kraynak et al., 2018).

In specific consideration of P_4 and T, exaggerated intracellular expression of the heat shock protein 90-bound immunophilin, FKBP51, diminishes high affinity intracellular binding of these steroid hormones and subsequent formation of transcription complexes by respective cytoplasmic or nuclear P_4 (PR) or androgen (AR) receptors. Increased expression of heat shock protein (hsp) in OWP usually only occurs when cells are exposed to altered protein folding, such as during heat exposure or malignancy, and buffers the cells from succumbing to apoptosis, oxidative stress or a variety of cell death mechanisms triggered by immune responses. Accompanying diminished expression of FKBP52, a molecular chaperone enabling high-affinity receptor binding and transcription complex formation, reinforces this intracellular block. Since FKBP51 expression, at least, is regulated by both P_4 and T, these contrasting differences between NWP and OWP molecular engagement of P_4 and T suggest accompanying contrasting differences in rapid, cell-specific ultrashort feedback loops regulating PR- and AR-mediated signaling.

Diminished NWP E_2 -mediated gene transcription, however, is accomplished by different, but analogous, intracellular mechanisms. Exaggerated expression of hsp27, also called HspB1, diminishes high affinity binding of E_2 and formation of transcription complexes by estrogen receptors (ER) ERalpha and ERbeta. In addition, over-expression of another intracellular binding protein, estrogen response element-binding protein (ERE-BP), also called heterogeneous nuclear riboprotein C-like 1 (hnRNP C-like 1), an RNA splicing repressor binding microRNAs, further contributes E_2 insensitivity. ERE-BP competes with classic, E_2 -bound ERalpha and ERbeta assembled transcription complexes for ERE-DNA binding sites around or within target genes. Such transcriptional

repression and decoy cytoplasmic binding are both overcome with elevated circulating levels of E_2 . E_2 -ER displacement of ERE-BP from DNA, however, liberates the RNA splice repressor to alter RNA splicing that may include its binding to microRNA and its interactions with intra-cellular proteins.

These complex intracellular molecular differences between NWP and OWP are still not fully understood in terms of steroid hormone action, and are particularly of interest as they also play key roles in cellular responses to cancer. Both OWP and NWP, however, differ from many non-primates in using the delta-5 steroidogenic pathway to derive androgens. In other words, anthropoid primate dehydroepiandrosterone (DHEA) is the major precursor for androstenedione (A_4) and T, not 17-hydroxyprogesterone. This becomes important when treating aspects of infertility and hormone abnormalities in primates.

Male Reproductive Physiology

Pituitary LH (all except NWP) or CG (NWP) acts on testicular Leydig cells to metabolize cholesterol into T, while FSH acts on Sertoli cells located within testicular seminiferous tubules, enabling their responsiveness to T and their metabolism of T into E_2 crucial for nurturing male germ cells into spermatozoa (sperm) and for their transport to the epididymis for maturation into motile, fertile germ cells. Epididymal sperm are ejaculated with prostatic and seminal fluids. Sperm maturation cycles in nonhuman primate testes, however, are not organized into synchronized tubule segments, in contrast to mice and rats.

In addition to its actions within the testes, T is released into the blood to differentiate and support species-typical male body structures and functions, including behavior, and to provide negative feedback control on hypothalamic GnRH and pituitary LH or CG to assure optimal (homeostatic) circulating levels of T. As AR and ER are both involved in mediating testicular T negative feedback on GnRH release in male nonhuman primates, and GnRH neurons do not express AR or ER, local hypothalamic conversion of T to E_2 completes feedback action through neighboring kisspeptin and neurokinin B neurons that synapse on to GnRH neurons. In adult males, kisspeptin and neurokinin B neurons do not exhibit integrated regulation of GnRH, in contrast to females (Garcia *et al.*, 2017). The testes, alone, produce insufficient circulating levels of E_2 to fully complete negative feedback control without contributions from testicular T and hypothalamically-derived E_2 .

While GnRH also stimulates FSH synthesis and release from pituitary gonadotropes, and thus negative feedback regulation of GnRH contributes to FSH release, testicular Sertoli cells synthesize and release inhibin B that specifically engages the majority of FSH negative feedback regulation at pituitary gonadotropes, alone. Inhibin B does not cross the blood-brain barrier and does not regulate GnRH. This additional negative feedback on FSH is required to ensure optimal FSH stimulation of spermatogenesis-nurturing Sertoli cells.

From experiments with fetal rhesus macaques, *Macaca mulatta*, negative feedback control in males develops by mid-gestation, in contrast to sometime after birth in females. Rising fetal T levels, released from the fetal testes, program male hypothalamus to respond only to ~5 times the concentrations of E_2 that are required in females to engage negative feedback control. This ensures considerably higher circulating levels of T compared to females because of the need to differentiate and support male phenotype. When female rhesus macaque hypothalamus are re-programmed to a male-like hypothalamus by experimental administration of T before mid-gestation, higher than normal levels of GnRH and LH become the norm because ovarian hormones, alone, are insufficient to fully control re-programmed negative feedback. As adults, ovaries of such gestational T-exposed females produce and release too much T, partly because of increased circulating levels of LH (Barnett and Abbott, 2003).

Positive feedback, a response that drives ovulation in females, is retained in the hypothalamus of male anthropoid primates. This is in complete contrast to male non-primate mammals in which T conversion to E_2 in the fetal male hypothalamus during sexual differentiation eradicates any positive feedback response in addition to programming for male-like behavior. In fetal anthropoid primates, androgens perform these roles. Male nonhuman primates, such as New World common marmosets (*Callithrix jacchus*) or Old World rhesus macaques, release a surge of LH in response to rapidly increasing concentrations of E_2 in the blood. Such blood E_2 dynamics are normally only produced by dominant, pre-ovulatory ovarian follicles in order to trigger a GnRH-induced LH surge that will ovulate one or more oocytes from within pre-ovulatory follicle(s). Consequently, when adult male rhesus macaques receive ovarian transplants, they spontaneously exhibit ovulatory cycles, confirming the absence of an otherwise typical sexual dimorphism in mammalian reproduction.

Male Mating Systems Determine Male Reproductive Attributes

In most, but not all, nonhuman primate species, adult males are larger than adult females. At one extreme is the flamboyantly colored male mandrill, *Mandrillus sphinx*, from west Africa weighing in at 30–35 kg, over three times the size of mandrill females, while at the other is the diminutive, monochromatic male common marmoset, *Callithrix jacchus*, from northeastern Brazil weighing in at 0.3–0.4 kg, equaling that of marmoset females. Robust sexual selection is responsible for the standout appearance of male mandrills, in contrast to its meagre presence in marmosets (Dixon, 2012). Mandrills live in multi-male troops or male-only groups, in which multiple males mate with a female when she is most fertile, around the time of ovulation, and exhibit seasonally-heightened, intense competition for access to breeding females. Male marmosets, on the other, usually live in extended, single family groups, in which male competition for breeding females is considerably less, probably due to the need for breeding males to contribute substantially to infant care, including carrying paternal twins, the usual birth quotient, from within a few minutes of birth.

Socially dominant, male nonhuman primates living in multi-male mating systems or in dispersed, small group mating systems exhibit T-dependent increased body size that can include pronounced body or scrotal coloration, body appendages such as facial phalanges, relatively large testicular sizes for their body weight, and large numbers of highly motile sperm (powered by enlarged mitochondria-containing midpieces) in voluminous ejaculates that plug up a female's vagina (Anderson and Dixson, 2002). The ability to repeatedly produce such ejaculates with high concentrations of motile sperm enable a male to continue competing against its rivals from within the mated female's reproductive tract and gain first access to an ovulated oocyte, and thus male reproductive success. Complex penile morphology and copulatory patterns, including multiple intromissions or prolonged intromission prior to ejaculation, also contribute to competitive strategies when more than one male mates the same female in quick succession.

Relatively meek, socially subordinate males in multi-male mating systems have developed 'sneaky' strategies to mate fertile females, including befriending females, i.e., low-ranking male rhesus macaques, or forceful mating ('raping') females, i.e., low-ranking male orangutans (*Pongo* spp.). Subordinate males diminish attracting the wrath of high-ranking males by minimally developing species-specific male attributes, such as color (mandrills) or facial phalanges (orangutans) (Setchell and Dixson, 2001). From genetic testing of free-ranging populations of nonhuman primates with multiple male mating systems, however, both dominant/overt and subordinate/sneaky male mating strategies garner reproductive success for both types of males.

Family-dwelling, breeding male marmosets, at the opposite end of this male attribute spectrum, ejaculate less frequently and usually only with their breeding female around the time of ovulation. Conception occurs, nevertheless. Single, relatively short duration penile intromission is typical of sexual intercourse among these more monogamous, single breeding male and female mating systems when considerably less male competition for females is the norm.

Male muriqui (*Brachyteles* spp.), living in multi-male and female groups in the Atlantic coastal forests of Brazil, bring a fascinating variation to the multi-male mating system (Strier, 1994). Male muriqui usually do not migrate between groups, so most males within a group are related. Within group males commonly embrace one another as a means of strengthening their egalitarian relationships. Male muriqui mate with multiple females, have relatively large testes, but do not physically compete for females. Male competition appears limited to sperm interactions within a female's reproductive tract.

Typical of male mammals, pre-optic, anterior and ventromedial hypothalamic areas of the brain are crucial for male sexual interest and sexual behavior, at least in NWP marmosets and OWP rhesus monkeys. Brain lesions in these areas eliminate male marmoset sexual interest in and behavior with female partners, while their reproductive physiology is otherwise normal.

Female Reproductive Physiology

At the beginning of each ovulatory cycle, pituitary LH (all except NWP) or CG (NWP alone) acts on theca cells in sufficiently mature ovarian follicles to metabolize cholesterol into androstenedione (A_4), an androgen with little bioactivity. The ovary, unlike the testis, favors production and release of a non-potent androgen to convert into estrogen, with little risk of developing male-like characteristics. A_4 is converted into E_2 within the same follicles by the neighboring inner layer of granulosa cells that nurture a single oocyte. During the early-to-mid follicular phase, FSH alone acts on granulosa cells stimulating them to release inhibin B in addition to E_2 . A few (all, except OWP and most NWP), or one (OWP and most NWP) of these follicles, undergo selection into a dominant follicle(s). A dominant follicle expresses LH receptors on its granulosa cells in addition to those for FSH, enabling its continued growth and maturation. Remaining non-dominant follicles become atretic due to inhibin-driven suppression of FSH. Onset of granulosa cell LH receptor expression also initiates gradual luteinization, a phenotypic change of theca and granulosa cells into cells emphasizing production of P_4 over E_2 . Dominant follicles contribute to the clamp on FSH release through an LH- (or CG-) mediated switch to inhibin A production. Rapidly rising circulating E_2 levels from dominant follicles trigger a positive feedback response, instigating greatly elevated release of LH (or CG) that triggers ovulation of an oocyte and its surrounding layer of specialized granulosa cells, cumulus cells, from each dominant follicle, and completes the conversion of theca and granulosa cells into the luteal cells of a corpus luteum (CL), predominantly secreting P_4 . Nonhuman primate CLs, unlike their non-primate counterparts, recover their ability to produce and release A_4 (luteinized theca cells) and E_2 (luteinized granulosa cells). They also continue to secrete inhibin A, clamping FSH at low levels. There are no uterine derived sources of luteolysis. Nonhuman primate CLs have endogenous biological clocks that progressively disengage luteal cell responsiveness to pituitary LH (or CG). High levels of embryo-produced CG are needed to 'rescue' the CL to support early pregnancy until the fetal placenta eventually assumes this role (Table 1).

Hypothalamic GnRH, in an analogous fashion to males, governs female nonhuman primate reproductive physiology. In contrast to males, negative feedback regulation engages after birth and is responsive to lower circulating levels of steroid hormones, particularly E_2 and P_4 , and positive feedback engages at puberty to regulate each ovulation. In contrast to non-primate female mammals, GnRH and surrounding neurons in the medial basal hypothalamus, alone, mediate feedback regulation in nonhuman primate females, and anterior pituitary gonadotrope cells exhibit E_2 -induced positive feedback LH surges without requiring a preceding GnRH surge. Negative feedback includes integrated hypothalamic kisspeptin and neurokinin B neuronal regulation, again in contrast to nonhuman primate males. Interestingly, ovarian and extra-ovarian (likely hypothalamic) production of E_2 provide separate, additive contributions to negative feedback (Kraynak et al., 2018). Production and release of E_2 from the hypothalamus is even more crucial for positive feedback, as blockade of E_2 synthesis at the site of hypothalamic GnRH release prevents rapidly rising circulating E_2 levels from eliciting an ovulation-inducing LH surge (Kenealy et al., 2017). Such distinct neuroendocrine regulation of female nonhuman primate reproduction in anthropoid

primates may have accompanied a degree of emancipation of reproductive physiology and behavior from the dictat of neuro-endocrine determination in non-anthropoid primate and non-primate females.

Female Phylogeny Aligns With Estrus, Ovarian and Menstrual Cycles

Estrous cycles, typical of the more ancient form of female reproductive cycle common to many non-primate mammals, predominate in lemurs, lorises and tarsiers. Elevated ovarian E_2 from one or more dominant follicles immediately preceding ovulation dictates 4–5 day opening of the vagina to accompany onset of female sexual behavior and receptivity to males, or estrus (Bogart *et al.*, 1977). Female sexual behavior and patent vagina only occur during this limited, E_2 -determined period of time, but there are species exceptions to vaginal closure outside estrus, e.g., ringtailed lemur, *Lemur catta*. Estrus is usually accompanied by changes in female genital scent and color, lasts ~1–8 days, and all aspects are attractive to males. Lemurs, lorises and tarsiers have well-developed vomeronasal organs in both sexes, and thus employ a substantial secondary sense of smell, particularly for non-volatile molecules, that directly alters behavior and physiology without engaging cognitive processing. Mating with a male, however, is not necessary for ovulation to occur. Photoperiod-entrained, annual synchrony of estrus is best demonstrated by Malagasy lemurs: all conceptions occur within one, 4–8 week period each year (Pereira, 1991). Progesterone secreted by the CL inhibits female estrous behavior. Estrus cycles are relatively lengthy at 33–40 days, reflecting a prolonged pre-estrous phase, without obvious elevations in circulating E_2 , and there is a distinct post-ovulatory P_4 -dominated luteal phase. It is unclear how female lemurs, lorises and tarsiers physiologically recognize conceptive cycles.

Ovarian cycles, in contrast to estrous cycles, do not rigidly constrain ovarian and extra-ovarian E_2 -supported vaginal opening or periods of female sexual behavior to periods of estrus. Ovarian cycles are exhibited by small-sized NWP, including marmosets and tamarins. Marmosets and tamarins typically ovulate two pre-ovulatory follicles per cycle, resulting in dizygotic or paternal twin gestations that share a placental circulation and the twins are hemopoietic chimeras. Non-mensing, female anthropoid primates do not require the substantial, highly vascular uterine endometrium of mensing female anthropoids because their placentae invade the uterine endometrium less aggressively to establish maternal-embryo/fetal nutrient, fluid and gas exchange. Following an internal clock-driven demise of CL(s) at the end of each luteal phase, an E_2 -dominated follicular phase comprises FSH-driven follicular recruitment that induces a growth spurt in ~6–20 non-dominant, medium-sized antral follicles per ovary. Selection of a species typical number of dominant follicles occurs around mid-follicular phase from the largest follicle(s) at that time in both ovaries combined. The consequent post-ovulatory formation of one or more CLs reflects the number of E_2 and LH/CG-driven ovulations for that cycle. In common marmosets at least, non-conceptive luteal phases (no pronounced rise in circulating levels of CG or ultrasonographic visualization of embryo sacs) can be lengthy in duration, lasting up to 29 days, approximately double that more commonly found among anthropoid female primates. As common marmosets frequently ovulate with 2–3 weeks of giving birth, and there is no lacion-induced anovulatory period typical of anthropoid primate females, marmosets carry two pregnancies each year. CL demise may therefore be less tightly controlled. Environmental and kin selection pressure on marmosets in their semi-arid, changeable and highly predated habitat of northeastern coastal Brazil may well have driven development of cooperative breeding and unusual high fecundity (Kraynak *et al.*, 2018).

Many NWP and OWP exhibit menstrual cycles, during which the end of luteal phase is marked by shedding of previously highly vascularized endometrial tissue through the vagina. The first day of menstrual bleed denotes the first day of the menstrual cycle. The endocrine dynamics of the follicular and luteal phases, and peri-ovulatory period, closely resemble those observed in ovarian cycles, and selection of a single dominant follicle is the norm. Peri-ovulatory changes in genital scent (marmosets), color (rhesus macaques) or swelling (chimpanzee spp.), or changes in chest color (Gelada baboons, *Theropithecus gelada*), attract attention and mating from male conspecifics, but females can copulate throughout the menstrual cycle.

Typical of female mammals, pre-optic, anterior and ventromedial hypothalamic areas in the brain are crucial for female nonhuman primate sexual solicitation of and receptivity towards males. Lesions in these brain areas eliminate female marmoset sexual solicitation (pre-optic) and receptivity (ventromedial).

Ovarian Androgen Excess as a Beneficial Female Phenotype

A variety of female nonhuman primates employ ovarian androgen excess during female fetal development to epigenetically reprogram (“organize”) multiple organ systems enabling better survival, fertility and fecundity. These naturally occurring attributes are further enforced (“activated”) by continuing ovarian androgen excess in adulthood. Unlike non-primates such as spotted hyenas, *Crocuta crocuta*, however, androgenized female nonhuman primates only comprise portions of a female population, not all. Lemur species commonly employ this high T female polymorphism (genetically determined) or polyethism (epigenetically determined) to dominate males, develop enhanced body size, vigorous play, and male-like, but vagina patent, external genitalia (Petty and Drea, 2015).

Studies of female macaques, however, suggest that elevated T in female nonhuman primates may have limits to its benefits. Fetal female rhesus macaques, whose mothers were exposed to T injected during early-to-mid gestation, frequently exhibit as adults ovarian hyperandrogenism, infrequent or absent menstrual cycles, impaired fertility, abnormal hypothalamic-pituitary regulation of ovarian function and metabolic dysfunction, including increased risk for type 2 diabetes mellitus (T2DM). Interestingly, these

traits emulate those found in women with polycystic ovary syndrome (PCOS). About 15% of women exhibit PCOS and usually have T levels that exceed the 95th percentile for female values. Origins of PCOS in women is unknown and there is no cure. In animal models, however, including nonhuman primates, PCOS-like traits are reliably epigenetically programmed by gestational exposure of females to higher-than-normal T levels. Consistent with a developmental origin hypothesis for PCOS, captive adult female rhesus macaques with naturally occurring circulating T levels above the 95th percentile mostly fail to get pregnant (Abbott *et al.*, 2017). These females also emulate neuroendocrine and ovarian abnormalities found in PCOS women, including a positive correlation between circulating androgen levels and anogenital distance, a biomarker for fetal T exposure. Improved understanding of high T in nonhuman female primate reproduction is providing novel insight into PCOS-like origins and its molecular pathogenesis (Barnett and Abbott, 2003).

Knowledge of Nonhuman Primate Reproduction Translates into Benefits for Conservation and for Humans

Increasingly non-invasive sampling, e.g., body hair, feces and urine, as well as sensitive and specific analytical techniques, e.g., tandem mass spectrometry, are enabling detailed understanding of reproductive function in both free living and captive nonhuman primates. Such accurate information is transforming efforts to better manage threatened and endangered populations in the wild, together with improved captive breeding program success (Jurke *et al.*, 1997).

The many shared similarities in genetics, physiology, development and aging between nonhuman primates and humans have also contributed to an impetus to better understand nonhuman primate reproduction and its potential application to human health. Researchers have developed intracytoplasmic sperm injection (ICSI) in a variety of nonhuman primates, including marmosets, rhesus macaques and yellow baboons (*Papio anubis*), in combination with assisted reproductive technologies (ART) to generate multiple pre-ovulatory follicles, enabling aspiration of high quality oocytes, and successful *in vitro* fertilization and embryo transfer resulting in term deliveries of healthy infants. Genome editing technologies, such as CRISPR-Cas9, are being used to create point mutations in marmoset embryos, such as in the LRRK2 gene associated with familial inheritance of Parkinson's disease. Such gene changes are permanently maintained, and infants carrying the desired mutation are being utilized for developmental studies aimed at developing treatments and therapies that can be translated into clinical practice (Sasaki, 2015).

Deer Reproduction

Geoffrey W Asher, AgResearch Ltd., Mosgiel, New Zealand

© 2018 Elsevier Inc. All rights reserved.

Distribution and Diversity of Cervids

While the taxonomy of cervids is often debated (particularly at the species/sub-species level), according to [Whitehead \(1993\)](#) deer are represented by 43 species and 206 subspecies distributed widely across Europe, Asia, North America, South America and northern Africa. Their evolution and geographical radiation over the last 20–40 million years has resulted in remarkable diversity in morphology, physiology, and ecology. In particular, reproductive strategies amongst cervids vary widely within and between regions. As such, no one species can be considered to represent a ‘typical’ deer in terms of reproductive function. For example, some cervids exhibit highly seasonal patterns of birth in cool temperate climes, while others are aseasonal in equatorial regions. Also, while many species are strictly monovular and bear single offspring annually, others are normally polyovular and bear multiple offspring. Even embryonic development and placentation vary amongst species ([Asher et al., 1999a,b](#)). [Harrington \(1985\)](#) expressed this variation in terms of ‘life-history strategies’ in which cervids can be classified into the two extremes; one maximises the reproductive capacity of individuals and the potential growth rate of the population (r), and the other maximises the competitive ability of individuals and the stability of the population (K). Unstable or early-successional habitats favour the r -strategy, while stable or late-successional (climax) habitats favour the K -strategy ([Harper et al., 1961](#)). The r -strategists are identified by their greater reproductive potential, exhibiting multiple births, early sexual maturation (<1 year) and short breeding life (<10 years). They are predominantly territorial browser- or concentrate-feeders adapted to rapid colonisation of early stage successional habitats; including species such as roe deer (*Capreolus capreolus*), whitetailed deer (*Odocoileus virginianus*), moose (*Alces alces*) and numerous species of tropical, forest-dwelling deer. K -strategists have lesser reproductive potential that includes lower fecundity (i.e., singleton births) and later sexual maturation (>1 year) and are generally mixed grazer/browsers with marked gregariousness and social/behavioural plasticity. They tend to occupy climax habitats and include nearly all taxa within *Cervus* (red deer, wapiti, sika deer, sambar deer, etc.) and *Rangifer* (reindeer, caribou). Because of their ability to adapt to human management regimens, it is the K -strategists that are predominantly represented in the research literature. It is therefore important to note that while there was an increased understanding of reproductive function in cervids over the last few decades, this relates mainly to those species of importance to agriculture (i.e., deer farming) and a few endangered species undergoing ex situ conservation efforts. In general, the research has been largely directed toward successful application of assisted reproductive technologies to manipulate the genetic composition of populations (e.g., selection for improved agricultural productivity and avoidance of inbreeding depression). The studies to date are clearly biased toward a few key species, particularly the larger-bodied, monovulatory species with greater environmental and behavioural plasticity (K -strategists) that makes them suitable candidates for captive propagation. The smaller-bodied, forest-dwelling and solitary species (r -strategists) are clearly under-represented in such research. This latter group includes numerous species whose populations are under threat or are endangered (see [Asher et al., 1999a](#)).

Seasonality Verses Aseasonality

The necessity for most cervid species to give birth at an appropriate time of year for optimal survival and growth of offspring has exerted considerable influence on their reproductive physiology ([Lincoln and Short, 1980](#)). Species of northern temperate or arctic origins typically conceive in autumn and calve in summer. In contrast, species of tropical origin often exhibit limited seasonality or are completely aseasonal ([Lincoln, 1985](#)). The endogenous mechanisms governing seasonal reproductive patterns in temperate species are robust, being manifest rigorously when animals are transferred between localities despite subtle variations in seasonal feed supply. The transference of temperate species across the equator results in an exact 6-month phase change ([Marshall, 1937](#)), even though the relationship between season and feed production differs considerably between continental northern hemisphere and insular southern hemisphere environments ([Asher et al., 1993a](#)). Tropical species transferred from equatorial zones exhibit either pronounced ‘reverse seasonality’ (spring conceptions and autumn/winter calving; e.g., rusa deer, *Cervus timorensis*, in southern Australia), wide birth seasons (e.g., chital deer, *Axis axis*, in Australia) or complete aseasonality (e.g., Reeve’s muntjac, *Muntiacus reevesii*, in United Kingdom) ([Chapman et al., 1984](#); [Loudon and Curlew, 1988](#); [Monfort et al., 1991](#); [Mylrea, 1992](#)). It is noteworthy that there is a general paucity of information on the birth season of tropical species in their native tropical environment, although there are well-documented examples of species that exhibit strictly seasonal patterns of birth.

For temperate and arctic species it is generally accepted that entrainment of seasonal reproductive cycles is effected by endogenous recognition of photoperiod changes, with the majority of species initiating mating activity during decreasing day-length of late summer and autumn ([Lincoln and Short, 1980](#)). Variations in the actual mating season between species of up to 8 weeks usually offsets differences in the duration of gestation, such that parturition generally occurs in mid-summer ([Lincoln, 1985](#)). A notable exception amongst temperate species is the Pere David’s deer (*Elaphurus davidianus*), which initiates mating activity in early summer and calves in late spring despite an unusually long gestation of ~280 days ([Wemmer et al., 1989](#)).

There is increasing evidence that some tropical species also perceive, and respond to, changes in photoperiod, although in a different manner than temperate species. Rusa deer living in the tropics exhibit asynchronous antler cycles and birth timings. However, once translocated to temperate, high-latitude zones they appear to establish an evolutionary-based 'long-day' reproductive rhythm (Van Mourik and Stelmasiak, 1990). Brow-antlered Eld's deer (*Cervus eldi thamin*) exhibit strong reproductive seasonality in their sub-tropical native range. This pattern persists after translocation to high latitudes (48°N), even though this strategy results in the birth of offspring during harsh winter months (Monfort *et al.*, 1991). It is hypothesised that Eld's deer respond to the relatively subtle low-amplitude photoperiodic oscillations experienced in their native subtropical latitudes. Higher latitudes simply serve to reinforce or strengthen seasonal rhythms because the direction of photoperiodic change is similar, just of greater amplitude. Chital deer appear to exhibit only limited seasonality within their native tropics and following translocation to temperate zones. However, exogenous melatonin treatment has been shown to hasten and synchronise antler casting amongst stags (Mylrea, 1992), indicating possible photoperiodic responsiveness in a species that, in other respects, appears unresponsive. In contrast, tropical sambar deer (*Cervus unicolor*) acclimatised to temperate zones in New Zealand exhibit a loose pattern of 'reverse seasonality' in calving but fail to show any discernible seasonal patterns in prolactin secretion (Asher *et al.*, 1997a).

Because tropical cervid species are not exposed to strong circannual photoperiodic rhythms, reproductive patterns may have evolved in response to a variety of factors including seasonal fluctuations in the availability of specific food items, local resource competition amongst sympatric species (species that occupy about the same area of land but do not interbreed), or predation pressure; and many of these factors may be directly related to rainfall patterns. For example, it has been asserted that conceptions are timed in white-tailed deer living in Columbia (5°N) and the Everglades National Park (25°N) so that births occur during the dry season (Blouch, 1987; Smith *et al.*, 1996). The fawning season of hog deer (*Axis porcinus*) in Nepal (27°N) coincides with new vegetative growth that occurs after seasonal grass fires caused by lightning strikes or agricultural burning, believed to have been occurring for thousands of years (Mishra and Wemmer, 1987). However, how these species synchronise their season of conceptions to achieve birth synchrony remains to be resolved. Even species like sambar deer and chital deer sharing the same habitat in Nepal fawn 6 months out-of-phase to one another (Mishra and Wemmer, 1987).

It is this lack of reproductive uniformity amongst sympatric species in the tropics and subtropics from which can infer differing adaptations to the environment based on a variety of regulatory mechanisms. In Nepal's Royal Chitawan National Park four cervid species co-exist, including two browsers (sambar deer and muntjac), one grazer (hog deer) and one mixed feeder (chital deer). Each of these species differs in their annual reproductive cycle, habitat selection and feeding ecology (Mishra and Wemmer, 1987). Although photo-responsiveness in tropical cervid species may persist as an evolutionary relic, the tight linkage between photoperiod and seasonal reproduction observed in temperate species may not completely explain the existence of reproductive seasonality in many tropical species.

Cervid species occupying wide latitudinal and longitudinal ranges have generally developed discrete populations that exhibit pronounced phenotypic and genotypic differences. For example the red deer/wapiti species (*Cervus elaphus*) includes at least 23 recognised subspecies in a west/east cline from Western Europe to North America (Whitehead, 1993). Climatic variation between subspecies zones may be associated with subtle variation in reproductive seasonality of the various subspecies. Studies have indicated that Western European (Scottish) red deer (*C.e. scoticus*) and Eastern European red deer (*C.e. hippelaphus*) farmed in New Zealand exhibit a 2–3 week difference in rutting activity and subsequent mean calving dates (Scott *et al.*, 2006). These differences occur at the same latitudes in both Europe and New Zealand (and indeed within sympatric populations on New Zealand farms), indicating subtle genetic differences in subspecies responses to the prevailing photoperiodic regimen.

Female Reproductive Cycles

With few exceptions, female cervids are polyoestrous, and non-pregnant animals are capable of exhibiting continuously repeated oestrous cycles (some tropical species) or, more commonly, alternating periods of oestrous cyclicity and anoestrus. Oestrous cycles have been characterised for a number of species from studies on oestrous behaviour and/or luteal secretion of progesterone. In non-pregnant females of temperate species, such as red deer and fallow deer, the onset and termination of oestrous cyclicity occur in autumn and spring respectively, with 5–8 cycles expressed. Anoestrus is characterised by low peripheral plasma concentrations of progesterone indicative of complete ovulatory arrest, and may persist for 4–6 months from spring to early autumn. In marked contrast, some tropical species, such as Brow-antlered Eld's deer and rusa deer, translocated to higher, temperate latitudes exhibit 'reverse seasonality', initiating oestrous cycles in spring and entering anoestrus in the following autumn. This 6 month phase shift in tropical species within temperate climes possibly indicates retention of photoperiodism from a temperate ancestral form. Some tropical species, such as chital deer appear to have become completely aseasonal, with females exhibiting free-running oestrous cycles in the absence of pregnancy (Mylrea, 1992). There are indications for some tropical species within temperate latitudes, such as sambar in New Zealand, that responsiveness to photoperiod has been lost, as indicated by an inability to detect measurable levels of plasma prolactin in sambar hinds during the year (Asher *et al.*, 1997a).

The transition into the female breeding season is characterised by 'silent ovulations' (ovulations not preceded by overt oestrus) and short-lived (8–10 days) corpora lutea in most cervid species studied. In fallow deer (*Dama dama*), multiple successive silent ovulations leading up to the start of the breeding season have been observed (Asher, 1985). The transient nature of the preliminary corpora lutea may actually serve to promote within-herd synchrony of first overt oestrus of the season.

Subsequent oestrous cycles are generally of normal duration, as determined genetically for each species, although occasional 'long cycles' have been observed in some Pere David's deer and Eld's deer (Curler *et al.*, 1988; Monfort *et al.*, 1991). Average

duration of the normal oestrous cycle ranges from 17 days in sambar and axis deer, 18–20 days in red deer and Eld's deer, 21–23 days in fallow deer, and 24–27 days in moose and blacktailed deer (*Odocoileus hemionus*). The mean duration of the oestrous cycle tends to increase progressively during the breeding season in most of these species (Guinness *et al.*, 1971; Asher, 1985; Curlewis *et al.*, 1988; Monfort *et al.*, 1991; Chapple *et al.*, 1993; Schwartz and Hundertmark, 1993; Wong and Parker, 1993).

Overt oestrous behaviour has been observed in a number of cervid species but the duration of mating receptivity at a single oestrus has been difficult to determine. In some species at least, including red deer and fallow deer, overt oestrus is generally terminated following successful copulation and may only persist for a matter of minutes. In the absence of copulation, oestrous behaviour in these species has been observed to occur for up to 24 h (Asher *et al.*, 1993b). Early studies on both of these species have shown that the onset of oestrus coincides with the onset of the pre-ovulatory LH surge, which itself peaks about 24 h before ovulation (Berg *et al.*, 1994, see Asher *et al.*, 1999a).

Luteal events during the cervid oestrous cycle are similar between species. Luteinisation of post-ovulatory follicles is associated with increased secretion of progesterone, with maximal concentrations in peripheral blood occurring between days 10 and 16 of the oestrous cycle (Day 0=oestrus). Although absolute plasma concentrations vary between species, the relative changes from Day 0 are quite similar between species (Asher *et al.*, 1999a). Luteal regression, which for fallow deer involves the classic interaction between oxytocin and prostaglandin F2a (Asher *et al.*, 1988a), occurs rapidly about 1–3 days before the return to basal progesterone concentrations and return oestrus.

Ovarian follicular dynamics during the oestrous cycle have been described from ultrasonographic studies on red deer, fallow deer and, more recently, North American Wapiti (*C.e. manitobensis*) (Asher *et al.*, 1997b, 1999b; McCorkell *et al.*, 2006). These studies, all of which involve monovulatory species, clearly demonstrated discrete, non-random patterns of antral follicular growth and regression during the oestrous cycle, with individual cycles characterised by 2–4 dominant follicle waves, similar to that observed in cattle.

Relatively little research has been dedicated to pregnancy establishment and maintenance in cervids. In the seasonally breeding red deer hind, conception rates following natural mating during the autumn rut appear to be high (>85% per mated oestrus), and early embryonic mortality (i.e., within 20 days of fertilisation) appears to be low (i.e., <1%; Berg *et al.*, 1994). Given that hinds are polyoestrus, under circumstances where nutrition and disease are not limiting, adult female red deer generally exhibit greater annual fertility (i.e., >96% pregnancy rates), albeit with lesser (i.e., <1% of pregnancies) twinning (Asher and Pearse, 2002). This overall pattern of greater annual fertility appears to be a common feature of many cervids, although actual fecundity varies between species. As expected for the greater fecund species, such as white-tailed deer and roe deer, the actual fecundity (i.e., incidence of multiple-foetus gestations) in a given year and locality is strongly influenced by habitat and nutritional quality variables.

Oocyte maturation, fertilisation and early embryonic development have recently been studied *in vivo* and *in vitro* for red deer (Berg *et al.*, 2008). These studies have shown that these events in red deer are similar to those occurring in other domestic ruminants, with the exception that the red deer embryo enters the uterus 2–3 days later at the blastocyst stage, 5–6.5 days after ovulation. Embryonic implantation in red deer occurs shortly before day 27 from ovulation (McMahon *et al.*, 1997).

Luteal support of pregnancy in red deer persist through the term of gestation, with peripheral blood progesterone concentrations remaining elevated to within 1–2 days of parturition. The contributory role of placental progesterone production in pregnancy maintenance is unknown. Studies on red deer and white-tailed deer clearly show that the presence of a functional corpus luteum is a requisite for a viable pregnancy (Asher *et al.*, 1996; Plotka *et al.*, 1982). However, ovariectomy of reindeer in late pregnancy was not always associated with abortion, indicating a possible contributing role of the fetoplacental unit in progesterone secretion and pregnancy maintenance in this species (Sjaastad *et al.*, 1990).

Importantly, these studies may not be representative of cervids in general. Placentation systems vary across cervid species (McMahon *et al.*, 1997), and in the case of one species, the roe deer, a form of embryonic diapause/delayed implantation occurs to lengthen the interval between mating and births in order to ensure optimal birth seasonality (Short and Hay, 1966). This is the only ruminant species known to exhibit delayed implantation.

Genetic and Environmental Control of Gestation Length

Cervid species have gestation lengths ranging from 200 to 280 days, loosely correlated with species mature live weight. There is a general underlying acceptance that gestation length for any given species is genetically programmed and relatively robust in the face of various environmental conditions. Recognition is given to the influence of foetal genotype as being the single most important determinant of gestation length: as well as determining interspecific differences in gestation length, it also accounts for subspecies and breed differences (Kenneth and Ritchie, 1953; Racey, 1981). Indeed, this has been demonstrated for the red deer species (*Cervus elaphus*) in which there is considerable subspecies variation in observed mating-birth intervals ranging from 233 days for Scottish red deer (*C.e. scoticus*) to 247 days for North American Wapiti (*C.e. nelsoni*, *roosevelti*, *manitobensis*) (Guinness *et al.*, 1971; Haigh, 2001). Red deer hinds gestating F1 crossbred red×Wapiti foetuses show a mating-calving interval of ~239 days (Asher *et al.*, 2005b). Similarly, although Pere David's deer, with a reported gestation length of ~280 days, are classified within a different genus, hybridisation with red deer hinds can result in fertile offspring. Hinds gestating F1 hybrid red×Pere David foetuses exhibit a wide range in mating-calving intervals from 262 to 274 days (Asher *et al.*, 1988b).

However, it has become apparent that gestation length within red deer subspecies is much more variable than previously thought (Asher, 2007). Guinness *et al.* (1978) noted a 5-day difference in mean gestation length between Scottish red deer hinds managed under differing nutritional regimens. More recently, Asher *et al.* (2005a) observed marked variation in gestation length

between hinds that were fed either greater or lesser amounts of nutrients during the third trimester of pregnancy. In that study gestation length was negatively correlated with change in hind live weight and the authors considered that under conditions of modest feed imbalance that appeared to influence foetal growth trajectory, a gestation length compensatory mechanism ensured optimal birth weight. In effect, the hypothesis argued that gestation length matched foetal growth rate to ensure optimum birth weight (possibly at the expense of optimal birth date).

Since the study of Asher *et al.* (2005a), other research has demonstrated a statistically robust association between conception date and gestation length for red deer subspecies. Garcia *et al.* (2006) observed that Spanish red deer hinds (*C.e. hispanicus*) that were artificially induced to conceive up to 68 days before the standard mating date exhibited longer gestation lengths than those conceiving later in the natural breeding season. They postulated that hinds were able to modify gestation length to counteract out-of-season breeding to optimise calving date. However, these previous data were confounded by the fact that early conceiving hinds exhibited lower live weight gains over pregnancy, thereby adding some support to the hypothesis of Asher *et al.* (2005a) that nutrition was a driver of gestation length variation. Most recently, Scott *et al.* (2008) investigated the relationship between conception date and gestation length in Scottish and Eastern European subspecies of red deer (*C.e. scoticus* and *C.e. hippelaphus*), using data for 393 naturally-mated hinds across two herds, as well as 91 hinds in which oestrus/conception were artificially synchronised across a 4-week range of dates spanning the natural rut. In all cases there were highly significant negative slopes for the regression of gestation length against conception date. Effects for hind age, hind live weight, calf gender, birth weight, sire genotype and year were not significant. The data supported a hypothesis that within-herd synchrony of red deer births is facilitated by a 'push/pull' control over gestation length, such that hinds conceiving early and late in the breeding season have longer and shorter gestation periods, respectively. The individual data sets indicate that for every 10 days difference in conception date there was a change in gestation length of 1.9–4.9 days. Recent studies by Scott *et al.* (2015) provide support for the hypothesis that variation in foetal age during the latter stages of pregnancy, when feed quality and voluntary feed intake cycles of dams are in a state of flux, drives differential growth trajectories for early and late conceiving foetuses, leading to nutritional control over foetal maturation and induction of parturition.

The aforementioned studies on red deer subspecies indicate a hitherto unexpected environmental control over gestation length in, at least some, cervids. Recent information indicates that this may also be the case for reindeer (Rowell and Shipka, 2009) and sika deer (*Cervus nippon*) (Matsuura *et al.*, 2004).

Environmental and Genetic Influences on Female Puberty

Female puberty, defined as the age of first ovulation, normally occurs between 1 and 3 years of age in most cervid species, although this is strongly influenced by climatic and nutritional factors. Such influences are mediated through body mass, as demonstrated for red deer hinds (Hamilton and Blaxter, 1980; Clutton-Brock *et al.*, 1982). Red deer hinds on New Zealand deer farms are expected to attain puberty at 16 months of age, and produce their first calf at 24 months of age. However, high incidences of reproductive failure within populations of rising-two-year old hinds (i.e., 10–60% of hinds not attaining pregnancy) have been common (Asher and Pearse, 2002), prompting research into factors controlling entry into puberty. Studies involving observations of over 20,000 young hinds have clearly shown a strong relationship between live-weight at 16 months of age and the ability to enter puberty (Asher and Cox, 2013), with hinds that fail to attain about 70% of the expected mature body-mass of their genotype (sub-species) by 16 months of age delaying puberty by at least one year. This has been termed as the 'permissive body mass threshold for entry into puberty' (Asher and Cox, 2013). While this has provided producers with live-weight targets to ensure a high proportion of the younger hinds attain puberty at 16 months of age, complications have arisen in the deer farming industry due to widespread and indiscriminate introgression of various sub-species that exhibit widely differing mature hind body mass phenotypes. The most extreme case is that involving the cross-breeding of Western European red deer (mainly *Cervus elaphus scoticus*), with a mature hind weight of 100–110 kg, with North American wapiti (mainly *C.e. nelsoni*, *roosevelti* and *manitobensis*), with a mature cow weight of 180–220 kg, to produce fertile cross-breds with an expected mature weight of 170–190 kg. The difficulties experienced with attaining high rates of puberty amongst the larger cross-bred hinds has been due to failure of the animals to reach the crucial body mass threshold required at 16 months of age (Asher *et al.*, 2005c). A similar issue has been observed in the introgression of Western European red deer with sub-species with less extreme mature body-mass differences, such as Eastern European red deer (*C.e. hippelaphus*), but, in general the '70% rule' applies to cross-bred genotypes. However, recent studies have provided support for the hypothesis that the nutritional environment in early-life (birth to 3 months of age) influences the permissive body mass threshold for puberty at 16 months of age. Detailed analysis of a multi-year dataset, in which the relationship between live-weight and predicted pregnancy rate was modelled, demonstrated that hinds under nutritional constraints early in life had a higher permissive body mass threshold for puberty for their genotype, raising intriguing possibilities self-regulatory mechanisms to control reproductive processes in the face of variable environmental (e.g., climatic and nutritional) conditions (Asher and Cox, 2013).

Male Reproductive Cycles

Circannual variation in testicular function is evident in most deer species, reflecting changes in fertility, gross morphometry and behaviour. Of the temperate species, these changes have been best described for red deer and fallow deer (see Asher *et al.*,

1999a,b). Episodic and pulsatile secretion of LH and testosterone change dramatically through the seasons, being maximal during 'rutting' (hyper-sexual activity by males around the short mating period in autumn). Similar patterns of secretion have been observed for Eld's deer, a tropical but seasonally breeding species (Monfort *et al.*, 1993).

Testosterone mediated changes in secondary sexual characteristics are very pronounced in both temperate and tropical cervid species. The antler cycle is linked closely to the testis cycle, with antlers cast annually when testes regress to their minimal dimensions. Casting is in response to a marked decline in testosterone secretion and can be induced by castration (Goss, 1983). New antler growth occurs during the quiescent phase of the testes, in the relative absence of testosterone secretion. Mineralisation (calcium phosphate deposition) of antlers coincides with increasing testicular activity and increasing testosterone secretion, and hard antlers are generally retained while testicular tissue is actively secreting modest to high amounts of testosterone. This relationship holds for most antlered species studied (Goss, 1983), although the seasonal patterns vary between species and the antler-testis cycles may not be synchronised amongst individuals of some tropical species (Loudon and Curlew, 1988).

Circannual patterns of testicular regression and recrudescence occurring in temperate cervid species relate to annual cycles of sperm production. Unlike most seasonally breeding domestic ruminants, which show moderate fluctuations in testicular activity (e.g., sheep), temperate cervids exhibit alternating periods of sperm production and complete spermatogenic arrest that reflect about fivefold changes in seasonal testicular volume (Lincoln, 1971). Although tropical cervid species often exhibit circannual cycles of reproductive development, either in a synchronous (e.g., Eld's deer) or non-synchronous manner (e.g., chital deer), males appear to retain a degree of fertility through-out the year (Loudon and Curlew, 1988; Chapman and Harris, 1991; Mylrea, 1992; Monfort *et al.*, 1993).

Conclusion

Clearly, there is no one 'model' species that defines typical cervid reproductive cycles, attesting to the complex array of life histories and reproductive strategies of the cervids in general. Our current understanding of reproductive biology largely centres around large-bodied, temperate (and highly seasonal) species that have a close association with man. In contrast, reproductive cycles of the smaller-bodied, tropical (aseasonal) species are generally poorly understood, with this group represented by many taxa that are at serious risk of extinction.

Glossary

Cloaca Cavity in the male tail that is used to release waste, sperm, and seminal fluid.

Cilia Hair-like cellular structures that extend into the extracellular environment.

Dauer An alternative life cycle stage that is migratory and resistant to harsh conditions.

Free-living Refers to nematodes that do not require a host for development and reproduction.

Insulin Growth factor ligand secreted from cells.

Notch Cell surface receptor for Delta ligands.

Oocyte meiotic maturation Process by which the oocyte prepares for fertilization.

Outcross Refers to progeny produced by mating to a male.

Polyunsaturated fatty acid Fatty acid chain containing 2 or more double bonds.

Prostaglandin Secreted lipid signaling molecule containing a 5-carbon ring structure.

Spermatheca Sac-like structure containing sperm where fertilization occurs.

Spermiogenesis Process by which sessile spermatids are converted into motile spermatozoa.

Steroid Lipid signaling molecule derived from cholesterol.

TGF- β Growth factor ligand of the transforming growth factor β superfamily.

Vas Deferens Male duct connecting the gonad to cloaca.

Vulva Hermaphrodite opening where eggs are laid and sperm are inseminated.

Introduction

Sydney Brenner introduced the nematode *C. elegans* to the biomedical research community more than 40 years ago (Brenner, 1974). Its simplicity in cell types, transparent epidermis, rapid generation time, and prodigious reproductive capacity makes this species well suited for studying the molecular genetics of animal development and behavior. Today, labs across the world conduct research on *C. elegans* to address fundamental questions related to developmental biology, reproductive biology, neurobiology, immunology, evolution, and human disease. The *C. elegans* genome is sequenced and annotated, its cell lineage and neural connectivity are described, and an arsenal of techniques is available to investigate gene function and regulation. These and other features have made *C. elegans* a popular choice for scientists and teachers.

C. elegans is a small (<1 mm in length), free-living roundworm found in soil and rotting vegetation, where it feeds on bacteria and other microorganisms (Frezal and Felix, 2015). In the lab, *C. elegans* is grown on agar plates seeded with *E. coli* (Corsi et al., 2015). Its life cycle consists of embryonic development, four larval stages called L1, L2, L3, and L4, and reproducing adults. To develop from a one-celled embryo into an adult takes 3–4 days, depending on the temperature. In the absence of food or in crowded conditions, *C. elegans* larva enter the dauer stage, an alternative life cycle where reproductive development stalls. Dauer larvae can survive harsh environmental conditions for several months.

C. elegans has two sexes, hermaphrodites and males (Fig. 1). During the L4 stage, the hermaphrodite gonad produces approximately 300 spermatids before switching to oocyte production. These spermatids form motile spermatozoa (termed sperm) that fertilize maturing oocytes during the first few days of adulthood until all sperm are consumed. Sperm are stored in the spermatheca, the site of fertilization. Embryonic development initiates in the uterus before eggs are laid through the vulva into the external environment (Fig. 1(A)). Hermaphrodites reproduce by self-fertilization (i.e., selfing) using sperm and oocyte from the same gonad.

Males are rare in the lab and nature, resulting from X chromosome nondisjunction during meiosis. Hermaphrodite selfing produces over 99.8% hermaphrodite progeny, which contain two X chromosomes. When a male and hermaphrodite mate, nearly all progeny will be outcross (i.e., fathered by the male) and approximately half will be male. The switch from self-fertilization to cross-fertilization is due to the competitive superiority of male-derived sperm. During mating, males use their tail (Fig. 1(B)) to

Fig. 1 Cartoon diagram of adult *C. elegans* hermaphrodite (A) and male (B) anatomy. Major tissues are indicated.

deposit sessile spermatids along with seminal fluid into the hermaphrodite uterus, where spermiogenesis occurs. Spermiogenesis triggers formation of the sperm pseudopod, a structure comprised of major sperm protein (MSP) filaments that drive locomotion. Motile sperm migrate over fertilized eggs and uterine cell membranes to the spermatheca (Fig. 1(A)). Sperm and oocyte secrete chemical signaling molecules that stimulate oocyte meiotic maturation and sperm chemotaxis, respectively. Below, we discuss important features of hermaphrodite and male reproductive development, mating, and fertilization in more detail.

Hermaphrodite Reproductive Development

The hermaphrodite gonad develops post-embryonically from a four-celled primordium, reaching sexual maturity about two days after hatching (Fig. 2) (Hubbard and Greenstein, 2000). The gonad primordium consists of two germ cells called Z2 and Z3 surrounded by two somatic gonadal precursor cells called Z1 and Z4. The germ line is formed during early embryonic development (Wang and Seydoux, 2013). Food is essential for gonad development, which also requires chemical signals from germ cells, somatic gonadal cells, and the nervous system. Gonadal cells start proliferating during the L1 stage, forming a tubular structure with a single distal tip cell (DTC) at each end. The DTCs promote gonad elongation during larval development, as well as promote germ cell proliferative fate. Ultimately, the hermaphrodite gonad forms into two mirrored U-shaped arms, one anterior and one posterior, that connect to a common uterus (Fig. 2). At the distal end of each arm lies a germline stem cell population that gives rise to differentiating gametes. Germ cells form a syncytium of shared cytoplasm called the rachis. As germ cells are displaced from distal to proximal positions, they enter meiosis and differentiate. The Notch signaling pathway controls germ cell fate. The Notch ligands LAG-2 and APX-1 are expressed in the DTCs, whereas the GLP-1 receptor is expressed in the germ cells. Disrupting Notch signaling causes all germ cells to enter meiosis. In addition to the DTC, Z1 and Z4 descendants form the gonadal sheath cells, spermatheca, uterus, and anchor cell, which is necessary for vulva induction.

Spermatogenesis starts during the L4 stage (Fig. 2) (L'hernault, 2006; Ellis and Stanfield, 2014). The first 30–40 most proximal germ cells in each gonad arm enter the spermatogenesis pathway. Primary spermatocytes bud off the rachis and enter meiosis I. The resulting secondary spermatocytes enter meiosis II to produce four haploid spermatids. Spermatids bud from an anucleate residual body that contains unneeded materials. In L4 stage and young adult hermaphrodites, spermatids are located in the proximal gonad arm. When the first oocyte undergoes meiotic maturation and ovulation, spermatids are swept into the spermatheca, where they rapidly undergo spermiogenesis. In hermaphrodites, spermiogenesis is regulated by the *spe-8* pathway, which is thought to respond to zinc signals.

Hermaphrodite gonads switch to oogenesis after spermatogenesis (Fig. 2). Germ cells enter meiosis and start progressing through prophase I. Not all meiotic prophase I germ cells will become oocytes. Some germ cells become nurse cells that help produce materials for the oocyte and embryo. Oocyte differentiation begins as germ cells progress from pachytene to diplotene stages of prophase I, near the bend in the gonad arm. Oocytes rapidly grow in size from provision of materials through the rachis and uptake of yolk, which is synthesized in the intestine. Oocytes are arranged in an assembly line in the proximal gonad with the most proximal oocyte adjacent to the spermatheca (Fig. 2). A valve prevents the oocyte from entering the spermatheca. Sperm

Fig. 2 Cartoon diagram of postembryonic gonad development during larval (L1–L4) and adult stages. The gonad primordia of freshly hatched L1 larvae contain Z2 and Z3 germline precursors that give rise to mitotic germ cells. During L3 and L4 stages, these cells enter meiosis and initiate spermatogenesis. Afterwards, all meiotic germ cells commit to oogenesis. The somatic gonad precursors Z1 and Z4 give rise to the distal tip cell (DTC), gonadal sheath cells, the spermatheca, and the uterus. See text for additional details. Gonad sizes are not drawn to scale.

secrete MSPs into the spermatheca lumen and proximal gonad. MSPs bind to receptors on oocyte and surrounding sheath cell surfaces, triggering oocyte meiotic maturation, sheath cell contraction, and ovulation. The most proximal oocyte ovulates into the spermatheca every ~25 min, while the next one back assumes the most proximal position. The gonadal sheath cells surround the developing germ cells and oocytes. Sheath cells are critical for germ cell proliferation, differentiation, meiotic progression, and ovulation.

The uterine lumen connects to the external environment through the vulva, a specialized opening composed of epithelial, neuronal, and muscle cells (Figs. 1(A) and 2). The vulva is required for egg laying and for entry of male sperm during mating. During larval development, the vulva is organized by the anchor cell, a descendant of Z1 and Z4. The anchor cell also patterns the uterine cells to form the connection with the vulva. Several evolutionarily conserved signaling cascades, such as WNT, epidermal growth factor (EGF), and Notch help pattern the vulva.

Male Reproductive Development

Morphologically, males have thinner bodies than hermaphrodites and a fan-shaped tail used for mating (Fig. 1). The male gonad consists of a single J-shaped tube that connects to a ventral opening in the tail called the cloaca (Hubbard and Greenstein, 2000; Emmons, 2005). Similar to the hermaphrodite gonad, the male gonad derives from a four-celled gonad primordium that divides during larval stages. Although males have two DTCs, they do not migrate. Instead, a specialized cell called the linker cell is responsible for gonad elongation. A germline stem cell population gives rise to meiotic germ cells that form spermatocytes, which detach from the rachis and complete meiosis. The resulting spermatids are stored in the seminal vesicle. The vas deferens connects the seminal vesicle to the cloaca (Fig. 1(B)). The TRY-5 trypsin-like protease is secreted into the seminal fluid, where it triggers spermiogenesis upon mixing with sperm during ejaculation.

Males also develop male-specific muscles and neurons for mating. During the L3 stage, six mesoderm cells divide to form 41 new muscle cells not found in hermaphrodites. Fifteen of these muscles run between the ventral and mid-lateral body wall and are used to curl the tail during mating. The male tail develops around the L4 stage. The anterior tail tip cells detach from the larval cuticle and retract, leaving behind a fluid-filled cavity. Nine rays then fan out into the cavity. These sensory rays house two sensory neurons each (Fig. 1(B)). The cloaca joins the intestine and gonad to the external environment via the cloacal opening. Two prong-like structures called spicules, the sensory rays, the hook, and the post-cloacal sensilla are all sensory organs that form in the male tail.

Mating

The majority of the sensory and motor behaviors associated with copulation are performed by the male. The male nervous system contains 383 neurons, 81 more than the hermaphrodite nervous system. Most male-specific neurons are in the posterior region and are thought to be involved in mating behaviors. Male mating behavior is complex and involves a series of steps (O'hagan *et al.*, 2014).

Prior to mating, the adult hermaphrodite secretes pheromones called ascarosides that cause an increase in male reversal frequency (Ludewig and Schroeder, 2013). This mating behavior requires chemosensory cilia formation in males, suggesting that males recognize ascarosides via chemoreceptors on sensory cilia. During mating, the male likely responds to both chemosensory and mechanosensory signals. When the sensory neurons in the male's tail contact a hermaphrodite, male response behavior is initiated. The response involves ceasing forward motion, placing the ventral side of his tail flat against the hermaphrodite's body, and moving backwards to scan for the vulva. It is mediated by the 9 pairs of rays in the male's tail. Each ray is made up of 1 structural cell and 2 sensory neurons. The dendritic processes of the 2 sensory neuron bodies span the length of each ray and terminate in ciliated sensory endings. Mutant males that are defective in sensory cilia formation have defects in mating response behavior, locating the vulva, and ejaculation. Males with mutations in the polycystin-1 homolog *lov-1* and polycystin-2 homolog *pkd-2* are defective in response behavior. Studies of *lov-1* and *pkd-2* were instrumental in establishing the association between human polycystic kidney disease and abnormal cilia function (O'hagan *et al.*, 2014).

If the male initially contacts the hermaphrodite on the dorsal side, he turns at the hermaphrodite's head or tail. This turning behavior requires sensory input from the ray neurons and is mediated by the male specific CP ventral cord motor neurons and EF interneurons. Male specific diagonal muscles, which are responsible for moving the tail, are innervated by the CP neurons. The neurotransmitters serotonin and dopamine are also required for turning behaviors. Exogenous application of serotonin causes ventral tail curling, comparable to that seen during mating. Dopamine or neuropeptide deficiency causes abnormal turning behavior.

The male locates the vulva on the ventral side of the hermaphrodite's body (Fig. 1(A)). Once the male contacts the vulva, he stops moving backwards, places his tail directly over the vulva, inserts his spicules, and ejaculates spermatids and seminal fluid into the hermaphrodite uterus. The hook sensillum mediates stopping, whereas the post-cloacal sensilla and spicules mediate tail positioning. The hook sensillum consists of a mechanosensory neuron, a chemosensory neuron, and two support cells. The post-cloacal sensilla are arranged as a bilateral pair with each sensillum composed of three neurons and three support cells.

Spicule insertion behavior begins when the male cloaca contacts the hermaphrodite vulva. Male-specific neurons and sex muscles located in the male tail coordinate this behavior. Spicules exhibit bilateral organization and individually contain portions of two sheath cells, four socket cells, and two sensory neurons wrapped in a sclerotized cuticle. Protractor and retractor muscles are associated with each spicule. Shortening of the protractors causes the spicules to stick out from the tail, and shortening of the retractors draws them back. The hook and post-cloacal sensilla trigger the protractors to begin periodic contractions. The spicule tips prod the vulva until they partially penetrate it, causing the protractors to contract completely so that the spicules extend through the vulva. After penetration, spicule movements stop until ejaculation is completed about 4 s later. The SPV neurons play a role in coordinating spicule penetration and ejaculation. Males that have undergone laser ablation of SPV neurons prematurely ejaculate during prodding behavior.

Gamete Interactions and Fertilization

For sperm and oocyte to successfully fuse, sperm must be in the spermatheca when an oocyte undergoes meiotic maturation and ovulation. Coordinating these events requires multiple intercellular signaling cascades (Han *et al.*, 2010; Ellis and Stanfield, 2014; Geldziler *et al.*, 2011). Developing oocytes located next to the spermatheca secrete lipid signaling molecules called prostaglandins that guide migrating sperm toward them. Sperm that enter the spermatheca are prevented from prematurely contacting immature oocytes by the distal spermathecal valve. Sperm compete for position next to the valve to be the first to contact the maturing oocyte during ovulation. Prostaglandins stimulate an increase in sperm migration velocity and prevent reversals during their journey through the uterus to the spermatheca. Once in the spermatheca, sperm are often pushed back out into the uterus by fertilized eggs passing through the spermatheca-uterine junction. Prostaglandins are thought to direct both hermaphrodite-derived and male-derived sperm, but the migration response by the latter is better understood. Prostaglandin synthesis requires 20-carbon polyunsaturated fatty acid (PUFA) transport from the intestine to the oocytes in yolk lipoprotein complexes. Oocytes secrete a heterogeneous mixture of F-series prostaglandins derived from multiple PUFA precursors. Prostaglandins are thought to form a concentration gradient within the reproductive tract.

Sperm alert oocytes to their presence through secretion of protein hormones called MSPs. These 126 amino acid polypeptides fold into an evolutionarily conserved immunoglobulin-like domain that has a conserved extracellular signaling function (Han *et al.*, 2010). MSPs bind to receptors on the oocyte and surrounding gonadal sheath cell membranes to induce oocyte meiotic maturation and sheath contraction. *C. elegans* oocytes, like those of most animals, arrest in meiotic prophase. Meiotic maturation is characterized by progression from prophase (or more specifically, diakinesis) to metaphase of meiosis I. It involves nuclear envelope breakdown, rearrangement of the cortical cytoskeleton, and meiotic spindle assembly (Greenstein, 2005). MSP binding activates heteromeric G-protein pathways in sheath cells and the mitogen-activated protein kinase cascade in oocytes, resulting in meiotic

maturation. The maturing oocyte secretes an EGF homolog called LIN-3 to induce distal spermatheca valve dilation. Meiotic maturation occurs about every 25 min in adult hermaphrodite gonads containing sperm, as oocytes initiate this process sequentially. MSPs have another major function as the cytoskeleton in the sperm pseudopod. The mechanism by which MSPs are secreted involves the budding of novel membrane-bound vesicles.

During ovulation, the spermathecal valve dilates and the oocyte enters the spermatheca. The sperm and oocyte then bind and fuse. SPE-9, a transmembrane protein containing an extracellular domain with 10 EGF-like repeats, is required in sperm for fertilization (Ellis and Stanfield, 2014; Geldziler *et al.*, 2011). *spe-9* null mutant sperm have normal morphology and motility, trigger oocyte meiotic maturation, and contact ovulating oocytes. SPE-9 is hypothesized to function as a ligand for an unidentified oocyte receptor. Consistent with this model, SPE-9 localizes to the pseudopod plasma membrane, the first structure to contact the oocyte plasma membrane. Mutations in several other genes have been characterized that give phenotypes similar to *spe-9* mutants. These genes include *spe-41/trp-3*, which encodes a TRP family calcium channel expressed on the sperm plasma membrane, and *spe-45*, which encodes a transmembrane protein with a single immunoglobulin-like domain. SPE-45 is similar in structure and function to Izumo1, a protein expressed in mouse sperm that is required for fertilization.

C. elegans oocytes were thought to lack a zona pellucida, a glycoprotein layer surrounding the plasma membrane involved in sperm binding. However, recent studies suggest that oocytes contain a thin basal lamina that may be analogous to a zona pellucida. Fertilization triggers a rise in oocyte intracellular calcium, completion of the meiotic divisions, extrusion of polar bodies, a polyspermy block, and egg shell formation. These processes are collectively referred to as egg activation. SPE-11 is a novel protein that is expressed in sperm and transferred to the oocyte during fertilization. *spe-11* loss does not impact fertilization, but it does impair egg activation events. In addition to a haploid nucleus, sperm also provide a pair of centrioles that form a centrosome. Oocytes lack a centrosome, which is required for mitotic spindle assembly. The sperm also specifies the posterior axis of the embryo via the Rho GTPase-activating protein CYK-4. Several genes have been identified that are expressed in oocyte cortex, where they regulate various aspects of egg activation. These genes encode proteins involved in protein phosphorylation, redistribution, and degradation. Thus, both paternally supplied and maternally supplied proteins help convert the oocyte into a dividing and differentiating embryo.

Embryogenesis can be broken into two major stages: a proliferation stage and an organogenesis/morphogenesis stage. The proliferation stage occurs during the first half of development until about 330 min post-fertilization and is further divided into two phases. The first phase covers the time from zygote formation to the production of embryonic founder cells. The second phase spans the majority of cell divisions and gastrulation. The embryo is laid into the external environment around gastrulation, which initiates at the ~26 cell stage. Gastrulation involves cell migrations, an increase in cell number, and cycles of concomitant stem cell divisions (Nance *et al.*, 2005). Gastrulation results in a spheroid-shaped embryo that is organized into three germ layers. The organogenesis/morphogenesis stage involves terminal differentiation of cells without additional cell divisions, threefold embryo elongation, and formation of fully differentiated tissues and organs. Following embryogenesis, the main body plan of the worm is fixed and does not change much during postembryonic development.

Environmental Regulation

C. elegans development and reproduction hinge on three environmental parameters: population density sensed through ascaroside pheromones, food supply, and temperature (Corsi *et al.*, 2015; Frezal and Felix, 2015). Environmental cues are detected through ciliated sensory neurons in the worm's nose and tail (Bargmann, 2006). Cilia extend into the external environment through pores and contain chemosensory G-protein coupled receptors that integrate specific signals into neuroendocrine pathways, such as TGF- β and insulin pathways. Temperature is sensed by the AFD neuron, which is also ciliated, and other thermosensory neurons.

In nutrient replete environments, the embryo hatches out of a virtually impermeable eggshell, and begins postembryonic development through the four larval stages. At the end of each stage, the animal molts and a new cuticle is made during the lethargus. Gonad development progresses as described above. However, when nutrients are scarce or pheromone levels are high, the larvae undergo a metabolic shift after the second molt and transition to the dauer stage (Hu, 2007). Dauers produce a specialized cuticle containing alae, block their mouth with an internal plug, stop pharyngeal pumping, and shift their metabolism toward the glyoxylate cycle to generate carbohydrates from lipid stores. Gonad development arrests, preventing reproduction. Dauer is a migratory stage that is resistant to harsh conditions and can survive for several months without food. Nutrient availability triggers the resumption of larval development and gonadogenesis, resulting in a fertile adult.

Genetic screens have led to the identification of genes that contribute to dauer entry and exit. These genes are divided into dauer-constitutive (Daf-c) and dauer-defective (Daf-d) classes based on their mutant phenotypes. There are four broad pathways that contribute to dauer.

1. The guanylyl cyclase pathway. *daf-11* is a Daf-c gene that encodes a transmembrane guanylyl cyclase expressed in amphid chemosensory neurons such as ASI, ASJ, and ASK. cGMP ions produced by *daf-11* modulate ion channels involved in thermosensation and chemosensation, including ascaroside detection.
2. The TGF- β pathway. *daf-7* is a Daf-c gene that encodes a TGF- β homolog expressed in ASI sensory neurons. DAF-7 expression is regulated by food and ascaroside levels. DAF-7 transmits signals through the DAF-1 type I and DAF-4 type II TGF- β receptors, which are broadly expressed. Further downstream are multiple SMAD class transcription factors.

3. The insulin pathway. *daf-2* is a Daf-c gene that encodes an insulin receptor homolog. DAF-2 transmits signals in the nervous system through a canonical pathway that includes the AGE-1 phosphoinositide 3-kinase catalytic subunit, PDK-1 and AKT-1/AKT-2 kinases, and the DAF-16 forkhead box O class transcription factor.
4. The steroid hormone pathway. The Daf-c gene *daf-9* and Daf-d gene *daf-12* encode proteins with similarity to cytochrome P450 class steroid hydroxylases and nuclear hormone receptors, respectively. DAF-9 helps synthesize steroid ligands called dafachronic acids, which bind with high affinity to DAF-12. The *daf-9/daf-12* pathway acts downstream of TGF- β and insulin pathways.

In addition to dauer, DAF-7 TGF- β and DAF-2 insulin receptor pathways also impact germline stem cell dynamics, oogenesis, and fertilization in late larval and adult stages (Hubbard *et al.*, 2013; Mcknight *et al.*, 2014; Lopez *et al.*, 2013). These mechanisms are thought to fine tune reproduction to nutrient levels. The DAF-7 pathway transduces signals in at least two gonadal cell types, the DTCs and germ cells. DAF-7 signaling to the DTCs negatively regulates DAF-3 Co-SMAD and DAF-5 Sno-Ski transcription factors, resulting in expansion of the germ cell progenitor pool. In adults, DAF-7 transmits signals through the nervous system and germ line to promote oocyte prostaglandin synthesis. As discussed above, prostaglandins provide sperm with positional information, ensuring that sperm target the spermatheca efficiently. Thus, increases in DAF-7 expression induced by food perception promotes gamete production and sperm function critical for fertilization. When nutrient levels are low or ascaroside concentration is high, reduced DAF-7 expression down-regulates these pathways, thereby reducing reproductive investment and output.

The DAF-2 pathway acts on oogenesis and prostaglandin synthesis (Lopez *et al.*, 2013; Han *et al.*, 2010). In the presence of food, DAF-2 activates the mitogen-activated protein kinase cascade to drive oocyte meiotic prophase I progression and oogenesis. DAF-2 signaling via the DAF-16 transcription factor promotes oocyte prostaglandin production. Ultimately, DAF-2 inhibits DAF-16 activity in the intestine and germ line, causing an increase in prostaglandin precursor flux into oocytes. Reduced DAF-2 signaling stalls oogenesis and inhibits sperm motility. Neurons are thought to secrete insulin ligands that regulate DAF-2 activity. The bacterial diet, temperature, oxygen tension, and other environmental factors also influence hermaphrodite and male fertility, but the mechanisms are less well understood or recently emerging. In summary, *C. elegans* uses multiple sensory circuits to integrate various environmental cues into developmental pathways governing gonadogenesis, gametogenesis, and fertilization.

Glossary

Chorion The insect eggshell.

Choriogenesis The synthesis and secretion of the chorion by the ovarian follicle cells.

Corpora allata Paired endocrine glands in the insect head that produce juvenile hormone.

Diapause A suspended development phase which is accompanied by a lowered metabolism.

Ecdysis The process of shedding the unresorbed, old cuticle.

Eclosion The ecdysis of the adult from the pupal stage.

Fat body The combined liver and adipose tissue of the insect.

Molt Synthesis of a new cuticle followed by resorption of most of the old cuticle, then ecdysis.

Ootheca Egg case of cockroaches.

Oviposition Egg laying.

Vitellogenin Yolk protein.

Vitellogenesis Includes both the synthesis of vitellogenin and its uptake into the oocyte.

Introduction

In insects reproductive maturation usually begins at metamorphosis in response to the steroid hormone ecdysone in the absence of the sesquiterpenoid juvenile hormone (JH). The immature state has been maintained by JH through the growth phase which is punctuated by periodic molts (production of a new, larger cuticle or exoskeleton followed by shedding of the old cuticle) initiated and orchestrated by ecdysone. In the lower insects such as cockroaches which molt directly from the last stage nymph to the adult, reproductive maturation occurs in the young adult. In the higher insects that have complete metamorphosis such as the tobacco hornworm and the fruit fly, some of the maturation occurs in the pupa, whereas the final steps occur in the adult. In both cases, at least in the females, JH is again secreted in the adult and regulates some aspects of reproduction which differ depending on the species being studied. Ecdysone from the ovaries may also be involved, again in different roles depending on the species.

This chapter will describe reproduction in four species commonly used in the laboratory: the fruit fly *Drosophila melanogaster*, the tobacco hornworm *Manduca sexta*, and two cockroach species *Blattella germanica* and *Diploptera punctata*. Both reproductive maturation and behavior and their regulation will be summarized.

Fruit Fly (*Drosophila melanogaster*)

At 25°C, the eggs hatch in 1 day, followed by 3 larval stages during which the larvae feed and grow, then wander out of the food and pupariate about 4 days after hatching. The puparium is the old larval cuticle which forms a protective covering for the formation of the pupa during the next 10–12 h. The adult emerges (ecloses) from the puparium 4 days later. The female is not receptive to the male until about 12–24 h after eclosion.

Male Reproduction

In *Drosophila* primary spermatocytes are first seen in the second instar larval testis, but meiosis and subsequent spermatogenesis does not begin until the prepupal period (Fuller, 1993). Thereafter, they continue throughout the male's life time. All stages of sperm differentiation are seen in squashes of adult testis. The stem cell niche at the apex of the testis contains both germline stem cells and cyst stem cells that support the differentiation of the germline stem cells into sperm. These stem cells require 20-hydroxyecdysone (20E) for their maintenance (Lie *et al.*, 2014). The source of the steroid hormone ecdysone in the adult male is not yet clear although the enzyme that converts ecdysone to 20E is expressed in the testis.

The male accessory glands produce peptides and proteins that are transferred to the female upon mating and diffuse into her hemolymph (blood) to play various roles in reproduction (Ravi Ram and Wolfner, 2007). A major player is the "sex peptide". This peptide binds to the sperm tails in the seminal fluid so first goes to the uterus, then is stored with the sperm in the seminal

receptacle and the spermatheca from which it is gradually released. It has two major functions: 1) to turn off female receptivity and thus mating behavior; 2) to stimulate the rate of JH production by the corpora allata. To turn off receptivity, sex peptide in the uterus decreases the activity of specific sensory neurons that are tonically active in the virgin females and activate specific abdominal neurons that relay the signal to the brain (Feng *et al.*, 2014). Loss of this signal turns off female receptivity. Sex peptide also directly activates JH release from the corpora allata; the role of JH will be discussed below in the section on Female Reproduction. In addition, sex peptide stimulates feeding activity by the mated female. Ovulin, another accessory gland protein, stimulates release of mature eggs from the ovary. Other accessory gland proteins are involved in sperm storage and maintenance.

Female Reproduction

At the time of metamorphosis, 16–20 ovarioles differentiate in each ovary, each of which has an apical germarium containing germline stem cells (Fig. 1). Oogenesis begins during adult development inside the pupa and continues throughout adult life. During oogenesis the germline stem cell divides asymmetrically to produce another germline stem cell and a daughter cell (Spradling, 1993). The daughter cell divides 4 times but the cells retain cytoplasmic connections and form a cyst of 16 cells that are interconnected through these “ring canals”. Two of these cells have connections with four other cells, and one of these becomes the oocyte. The others become the nurse cells that produce nutrients and cytoplasmic components such as mitochondria and ribosomes for the oocyte. The oocyte nucleus begins meiosis which subsequently is arrested in Prophase I during most of oogenesis. The cyst becomes surrounded by a single follicular cell layer. This follicle, usually called the egg chamber, separates from the germarium, and the oocyte matures into the egg through 14 stages. Yolk protein (vitellogenin) synthesis begins in stage 8, both in the follicle cells and in the fat body (the combined liver and adipose tissue of the insect), but is not taken up into the oocyte until stage 10. Vitellogenesis is completed by stage 11. In stage 11 the nurse cells dump their contents into the oocyte and the oocyte progresses to meiosis Metaphase I arrest. Chorion (egg shell) deposition occurs in stages 13 and 14 at the end of which ovulation occurs and meiosis is completed. The eggs are then fertilized as they are laid (oviposited).

At the time of adult eclosion, the female has partially mature ovaries in which oogenesis of the terminal oocyte in each ovariole has proceeded up to previtellogenic stage 8. Vitellogenin synthesis begins after emergence. Mature eggs are found on day 2, and maturation continues asynchronously throughout her lifetime as long as the female mates and feeds.

Both ecdysone and JH are involved in regulation of reproductive maturation in the adult female (Fig. 2). In the ovary, ecdysone is produced by the mature follicle cells at low levels beginning at stage 8 and is involved in several aspects of normal oogenesis (Bownes, 2005; Belles and Piulachs, 2015; Fig. 2). It is necessary both for continued proliferation of the germline stem cells and for their maintenance within the germarium. Ecdysone is also necessary for the onset of meiosis in the oocyte nucleus and for the initial follicle cell formation that occurs in the germarium. Later in stage 9 it causes the initiation of border cell migration between the nurse cells to form a boundary between the nurse cells and the oocyte. These border cells later contribute to the formation of the micropyle in the chorion which allows sperm entry. In stage 10, ecdysone is required to promote lipid uptake and accumulation in the oocyte. Finally it is required for choriogenesis (Papantonis *et al.*, 2015) and ovulation of the mature egg.

Fig. 1 Diagram of oocyte maturation within an ovariole of the panoistic ovary of the cockroaches *Blattella germanica* and *Diploptera punctata* and of the meroistic ovary of *Drosophila* and *Manduca*. In the panoistic ovary, only the terminal oocyte in each ovariole matures in each reproductive cycle. In the meroistic ovary, there is progressive maturation of the egg chambers (oocytes and associated nurse cells). FC, follicle cells; GE, germarium; NC, nurse cells; O, oocyte; TF, terminal filament.

Feeding on a protein-rich diet causes the release of insulin-like peptides from brain neurosecretory cells which directly stimulate stem cell proliferation and indirectly germ cell maintenance through effects on the ovarian stem cell niche (Das and Arur, 2017). Insulin action is independent of ecdysone action on these stem cells. If the females are starved or not given any protein, the oocytes at stage 9 begin to be resorbed rather than continuing their maturation (Bownes, 2005; Belles and Piulachs, 2015). This resorption was found to be mediated by increased ecdysone synthesis and accumulation in the ovary. When the females were fed after a period of starvation, the ovarian ecdysteroid level rapidly declined and vitellogenesis proceeded.

The synthesis and release of JH is activated at eclosion and continues thereafter (Bownes, 2005). JH is required for the rapid uptake of vitellogenin by endocytosis during stage 10 of oogenesis (Fig. 2). It is thought that JH stimulates the initiation of yolk protein synthesis in the fat body; but once this synthesis is turned on, its continuation does not require further hormonal stimulation.

JH also mediates the normal timing of mating which usually occurs one to two days after eclosion. In the absence of JH, both female receptivity to male courtship and the production of two female-specific sex attractants are delayed by at least two days (Bilen et al., 2013; Fig. 2). The finding that they are not prevented but only delayed indicates that other, yet unknown factors are involved in regulation of these events. After mating the sex peptide from the male turns off female receptivity as described above and increases both JH production and feeding in the female.

The increase of JH after mating causes remodeling of the midgut (Reiff et al., 2015; Fig. 2). The JH causes proliferation of the midgut cells followed by their differentiation so that the midgut becomes larger. JH also increases fatty acid synthesis and accumulation in the cells of the posterior midgut. These changes in turn lead to increased egg production.

Tobacco Hornworm (*Manduca sexta*)

In the wild tobacco hornworm larvae feed on the leaves of tobacco, tomato and other solanaceous plants, and the resulting moths feed on the nectar of these same plants. In the laboratory the larvae feed on an artificial diet that contains no plant material, but the moths require the plant for oviposition (egg laying). Virgin females begin “calling” (the protrusion of the ovipositor exposing the sex pheromone glands near the tip), thus releasing their pheromone, about two hours after lights-off in a long day photoperiod (16 h light: 8 h dark) (16L:8D) (Sasaki and Riddiford, 1984). At this time the males are flying; when they enter the pheromone plume, they fly upwind to find the female and mate. Mating occurs during the next few hours during the night and usually lasts about 3–4 h at 24°C. No plants are necessary for this phase. Eggs are not laid until the following night beginning at the time of lights off and continuing through the night. The females lay their eggs on the underside of the plant leaves. At 25°C, the eggs hatch four days later.

Male Reproduction

Male reproductive maturation in *Manduca* begins in the prepupal period. Primary spermatocytes can be seen in the penultimate larval testis, but maturation into eupyrene (nucleate) sperm starting with meiosis only begins in the prepupal period and is initiated by the rise of ecdysteroid that causes the pupal molt (Friedlander and Reynolds, 1988). The final maturation of the spermatids

begins in the early pupa and continues through the lifetime of the male. Lepidoptera such as *Manduca* also have apyrene (non-nucleated) sperm. These do not begin their development until early in the pupa. They are transferred along with the eupyrene sperm to the female during mating. Although apyrene sperm have been found necessary for male fertility in the silk moth, their precise role is still unknown (see [Friedlander \(2007\)](#) for a review of the various theories).

When *Manduca* larvae are reared under a short day photoperiod of 12L:12D, the resultant pupae undergo a pupal diapause (a suspended development phase accompanied by a low metabolic rate). Importantly, maturation of the eupyrene sperm begins as described above and proceeds up into early spermatid differentiation at which point continued development is blocked and these spermatids subsequently die ([Friedlander and Reynolds, 1992](#)). This process continues throughout diapause. In contrast, maturation does not begin in the apyrene spermatocytes which appear abnormal and subsequently die. Only when diapause is terminated by the secretion of ecdysone to cause adult development is normal spermatogenesis resumed in both eupyrene and apyrene sperm.

Female Reproduction

Egg maturation begins in the developing adult inside the pupa so that by the time that the adult emerges, she has partially mature eggs that have some yolk in the oocyte but retain the nurse cells ([Nijhout and Riddiford, 1974; Fig. 1](#)). Vitellogenin is synthesized by the fat body and first appears in the hemolymph (blood) 3 days before the adult emerges. Upon eclosion the corpora allata begin to produce JH which mediates full maturation of about 150 eggs in an unfed virgin female over the next week. The first mature eggs are found at 24 h after eclosion. Sucrose feeding increases the number of eggs matured to about 400 by 9 days, apparently by maintaining or increasing the JH secretion by the corpora allata. Neither the release of sex pheromone nor mating is dependent on JH ([Sasaki and Riddiford, 1984; Fig. 2](#)).

Mating increases the production of JH. The stretching of the bursa copulatrix by the spermatophore from the male that contains the male accessory gland secretions and the sperm sends a nervous signal to the brain ([Stringer et al., 1985](#)). This signal causes release of an allatotropin from several pairs of neurosecretory cells in the brain which in turn activates JH secretion. Consequently, a mated female that has access to a continued food supply can mature and lay up to 1400 eggs over her lifetime of two to three weeks.

The molecular basis of the action of JH in mediating egg maturation in *Manduca* has not been studied. In the absence of JH in the adult, the terminal oocyte in each ovariole (the female has 8 ovarioles) grows to about half of its final length and contains some yolk, then begins to resorb the yolk and die whereupon the next one in line matures to this critical stage ([Nijhout and Riddiford, 1974](#)). When JH is present, the oocytes take up yolk protein at a faster rate ([Fig. 2](#)); once sufficient vitellogenin is present, the oocyte hydrates to its final size and the chorion (egg shell) is deposited. How JH increases the rate of vitellogenin uptake is not known.

The role of ecdysone in *Manduca* female reproductive maturation has not been studied ([Fig. 2](#)).

Cockroaches

Two favorite laboratory species of cockroach in which reproduction is studied are *Blattella germanica* (the German cockroach) and *Diploptera punctata* (the Pacific beetle cockroach). In both cases, JH is the main regulator of reproductive maturation in the female ([Fig. 2](#)); male reproductive development begins at metamorphosis and appears to be largely unregulated in the adult. Each will be considered separately.

Blattella germanica

Blattella germanica are usually reared at 27°–30°C. on either dog chow or rodent chow. There are usually 6 nymphal stages followed by metamorphosis to the adult.

Male Reproduction

In *Blattella*, the male accessory glands that contribute to the spermatophore are at least partially regulated by JH since in its absence their protein content was at least 50% reduced ([Schal et al., 1997](#)). The onset of male readiness to mate is also delayed in the absence of JH.

Female Reproduction

At the time of adult ecdysis, the terminal oocyte in each of the 20 ovarioles per ovary is previtellogenic ([Schal et al., 1997; Fig. 1](#)). The female begins feeding and on day 2 at 27°C, terminal oocyte maturation begins. During the next few days, the female becomes sexually receptive and produces and releases her sex pheromone, and mating ensues. The egg case (ootheca) containing 40 eggs

is extruded partially from the female on day 9 but not released until 21 days later when the nymphs hatch. This 21 day period is called gestation or pregnancy. Maturation of the new terminal oocytes does not begin until the ootheca is released. The next ootheca is extruded 7 days later. These cycles repeat throughout the lifetime of the female which lives about 180 days.

In this cockroach, feeding after adult ecdysis is prerequisite for egg maturation since it is necessary for the onset of JH biosynthesis. Juvenile hormone is required for vitellogenic oocyte maturation as it stimulates vitellogenin production by the fat body and likely vitellogenin uptake by the oocytes (Fig. 2). In a fed female, JH synthesis and release begins on day one after adult emergence and continues throughout vitellogenesis, then declines during the final stage of choriogenesis to undetectable levels by the time of extrusion of the ootheca. No JH is produced during the time that the embryos develop; its synthesis and release begins again when the ootheca is released. In addition, JH stimulates the female accessory glands to produce the proteins that are necessary for production of the ootheca. The cessation of JH production during the gestation period is due to nervous inhibition from the brain but exact mechanisms are not known.

JH also is necessary for female sex pheromone production and for the female to become receptive to the male (Fig. 2). Mating causes the immediate cessation of both female receptivity and pheromone release due to presence of the spermatophore in the bursa copulatrix that sends a nervous signal to the brain; continued inhibition of both is due to sperm in the spermatheca.

Social interactions with other females accelerate reproductive maturation by increasing the rate of JH production. Under these conditions, there is a synchronization of oothecal extrusion by the females. However, overcrowding prevents this phenomenon.

Ecdysteroids are also involved in oogenesis in this species. Ecdysone from the follicle cells of the ovary induces choriogenesis once vitellogenesis is complete (Belles and Piulachs, 2015; Fig. 2).

Diploptera punctata

In the laboratory *Diploptera* are reared on lab chow at 27°C. Males have three nymphal stages while females have 4. The females mate immediately after adult ecdysis whereas the males usually do not court and mate until they are about a week old. The females are viviparous and retain their embryos in a brood sac until they hatch.

Male Reproduction

Diploptera males mature more slowly and normally do not show courtship or mating behavior for at least a week after adult ecdysis. The corpora allata produce a small amount of JH but accessory glands, spermatophore production and sexual behavior are normal in its absence (Tobe *et al.*, 1979). Further studies on the regulation of male reproduction have not been done in this species.

Female Reproduction

In virgin females, nervous inhibition prevents the synthesis and secretion of JH from the corpora allata (Marchal *et al.*, 2013). Upon mating, the presence of the spermatophore in the bursa copulatrix acts via the brain to relieve this inhibition and to activate JH production by the corpora allata. Mating also stimulates oocyte growth. There are 6 ovarioles in each ovary and only the terminal oocyte matures in each reproductive cycle. Vitellogenesis begins on day 2 with vitellogenin synthesis and secretion by the fat body and uptake into the terminal oocyte and continues until day 6. Then choriogenesis occurs, so by day 7, the eggs are mature and ovulated and fertilized, then covered by an incomplete ootheca. Instead of being extruded as in *Blattella*, the ootheca is retracted into the brood sac where embryonic development occurs. During this 63 day period, the brood sac produces “milk proteins” and carbohydrates for nourishment of the embryos which they drink during later embryonic development.

Juvenile hormone is necessary for both vitellogenin production by the fat body and its uptake by the oocyte (Fig. 2). As vitellogenesis nears its end, the corpora allata become sensitive to allatostatin from brain neurosecretory cells through an increase of allatostatin receptors and JH synthesis declines. During pregnancy no JH is synthesized. Synthesis begins again after the embryos are born, and a second cycle begins. The female accessory glands also require JH for the production of the ootheca.

Studies of the effects of the depletion of ecdysone receptors in female *Diploptera* have indicated that ecdysone is necessary for chorion formation and for ovulation of the eggs (Hult *et al.*, 2015; Fig. 2). Ecdysone is produced by the follicle cells during the later phases of oocyte maturation. It also seems to be involved in the shutting down of JH synthesis by the corpora allata at the end of vitellogenesis.

Acknowledgements

I thank Dr. James Truman for drawing Fig. 1 and comments on the manuscript.

Sea Urchins as Lab Animals for Reproductive and Developmental Biology

Amro Hamdoun, Catherine S Schrankel, Katherine T Nesbit, and Jose A Espinoza, University of California San Diego, San Diego, CA, United States

Early History of the Sea Urchin Embryo as a Lab Animal

The sea urchin has a rich history as a model organism, dating back to the mid 1800s (Table 1; reviewed in Ernst, 2011). Given the ease of gamete collection and embryo observation, the sea urchin became an important experimental model for 19th century scientists exploring the fundamental questions of development: What is the role of the nucleus in development (as sperm and egg each appear to have one)? What information exchange occurs at the union of egg and sperm? How does this enable the fertilized egg to blossom (or “differentiate”) into an adult organism that exhibits the same body plan, cell types and organs as the parents? Early studies in sea urchins overturned long-held theories of preformation – that a miniature individual is already encapsulated in totem within a sperm (the “homunculus”) – and demonstrated that the individual is formed by the fusion of nuclear material from both sperm and egg.

A Single Sperm for Every Egg

The sea urchin was used to study fertilization as early as the 1840s, by Derbs and colleagues (reviewed in Briggs and Wessel, 2006). In the later 1800s, using sea star and sea urchin eggs, Hermann Fol and Oscar Hertwig were the first scientists to observe that a single sperm penetrates the egg membrane during fertilization (Hertwig, 1877). Fol also observed that an envelope immediately forms around the egg, presumably to prevent additional sperm from fusing (known as “polyspermy”) (Fol, 1877). Fol and Hertwig also documented that the nucleus of a successfully penetrated sperm will fuse with the nucleus of the egg.

Table 1 Milestones and major discoveries in sea urchin embryology ~1875–2000s

Fusion of sperm and egg nuclei at fertilization; fusion of a single sperm with the egg at fertilization	Hertwig (1877), Fol (1877)
Demonstration of phagocytosis and foundation of the cellular theory of immunology (Nobel Prize 1908, Elias Metchnikoff)	Metchnikoff (1893)
Chromosomes in nucleus are determinants for development; individual chromosomes possess different qualities	Boveri (1902)
DNA is found in chromosomes and RNA is found in cytoplasm of all cells; first correlation of RNA and protein synthesis	Brachet (1945)
Isolation of the mitotic apparatus during cleavage	Mazia and Dan (1952)

The Nuclear Basis of Inheritance

Fol and Hertwig's work on pronuclear fusion illuminated that the zygote contains nuclear substance derived from both parents. Biologist Theodor Boveri subsequently demonstrated that nuclei were necessary for proper development of the fertilized egg. Boveri also characterized that a normal set of chromosomes in each cell is required for early development (Boveri, 1902). By watching chromosomes separate during mitosis of urchin zygotes, Boveri was the first person to make the giant conceptual leap to state that Mendel's factors of inheritance must be on the chromosomes. Around the turn of the 20th century, Hans Driesch also used sea urchin embryos to define the equipotent potential of early quadrants of the embryo ("blastomeres"). He showed that one blastomere isolated from a 2 or 4-cell stage sea urchin embryo can develop into a smaller, yet complete larva. These experiments were refined by Sven Horstadius in the 1930s who clarified the role of localized determinates in the egg (molecules that define future body axes) by splitting or stretching individual blastomeres or embryos along different axes and assessing developmental outcomes (reviewed in Ernst, 2011).

Sea Urchins Used in the Lab

Major Species Used and Their Experimental Advantages

Sea urchins are ancient marine invertebrates of Class Echinodea within the phylum Echinodermata. There are approximately 900 extant species of sea urchins distributed throughout the world's coastal oceans. Of these a handful have been used as lab animals, primarily *Strongylocentrotus purpuratus*, *Lytechinus variegatus*, *Arbacia punctulata*, *Hemicentrotus pulcherrimus* and *Paracentrotus lividus* (Table 2) which are native to the Pacific, Atlantic and Mediterranean Oceans. Several of these species have fully sequenced and publically available genomes (www.echinobase.org). Two other species, including *Lytechinus pictus* and *Temnopleurus hardwicki* are also useful as lab models, due their relatively small adult size and shorter generation times.

Table 2 Summary of species information and breeding season for select sea urchin lab species

Species name	Common name	Habitat range and temperature	Breeding season ^a	Egg diameter	Key developmental stages ^a (time after insemination)	
<i>Strongylocentrotus purpuratus</i>	Purple urchin	Alaska-Baja California; 12–17°C	November–March	80 µm	Blastula	16 h
					Gastrulation	30 h
					Pluteus larva	4 Days
					Metamorphosis	40–80 Days
<i>Lytechinus variegatus</i>	Green urchin	North Carolina-Bahamas; 20–25°C	May–September	120 µm	Blastula	6 h
					Gastrulation	11 h
					Pluteus larva	20–24 h
					Metamorphosis	30–40 Days
<i>Lytechinus pictus</i>	Painted urchin	Southern California; 18–22°C	May–September	120 µm	Blastula	6 h
					Gastrulation	24 h
					Pluteus larva	48 h
					Metamorphosis	30–40 Days
<i>Temnopleurus</i> species (<i>T. toreumaticus</i> and <i>T. reevesii</i>)	Japanese urchin	Western Pacific; Japan and China Seas; 22–26°C	July–January	100 µm	Blastula	8–10 h
					Gastrulation	11–12 h
					Pluteus larva	28–30 h
					Metamorphosis	30–33 Days
<i>Paracentrotus lividus</i>	Mediterranean urchin	Mediterranean Sea-Eastern Atlantic; 18–25°C	May–September	75 µm	Blastula	4 h
					Gastrulation	5 h
					Pluteus larva	24 h
					Metamorphosis	20–30 Days

^aReproductive cycles and time to metamorphosis may fluctuate, based on local environmental conditions; the earliest pluteus larval stage (2–4 arm) is indicated.

The purple sea urchin, *S. purpuratus*, was the first echinoderm species to have its genome sequenced, and is the most widely used in the lab. The genome of *S. purpuratus* is approximately 814 million bases in length and encodes 23,300 genes (Sodergren *et al.*, 2006). As basal deuterostomes, the branch of evolution leading to vertebrates, sea urchins share many genes with humans. Complete developmental transcriptomes from multiple stages of *S. purpuratus* development are publically available at www.echinobase.org. Roughly one third of urchin genes encode proteins that are found in humans. These include many genes that are responsible for human genetic diseases. Remarkably, sea urchins also have a diverse repertoire of genes involved in hearing and vision, the latter genes functioning in photoreception of the adult tube feet. They also exhibit a significantly expanded innate immune gene repertoire compared to vertebrates.

The defining feature of sea urchins as lab animals is their extreme fecundity. Ripe animals can be easily induced to spawn by gentle shaking, injection of potassium chloride (KCl) into the coelomic cavity, or by mild electric shock. In the case of potassium chloride, the potassium ions cause muscle contractions that expel gametes. During spawning, eggs or sperm are released through five gonopores located at the top (aboral) surface of the animal, encircling the anus. A gravid female purple urchin yields 5–10 mL of packed eggs, while males produce approximately 0.5–1 mL of “dry” (i.e., prior to dilution of seawater) semen. “Dry” *S. purpuratus* semen is consistently 4×10^{10} cells per mL. Eggs with jelly coats removed are 2.8×10^6 eggs per mL. Egg sizes vary from 70–150 μm in diameter depending on species (Table 2). Eggs can be maintained for several days in sea water containing antibiotic(s) such as ampicillin, sulfamethoxazole and/or trimethoprim to prevent microbial growth. Concentrated sea urchin sperm collected directly from the surface of the animal are immotile until diluted into sea water. If collected directly from the males, sperm can be stored for several days at 4°C.

Adult Anatomy and Anatomical Structure of Gonads

Sea urchins typically range in size from 6 to 12 cm. The largest species can reach up to 36 cm in diameter. Adult sea urchins have radial symmetry: the body is roughly spherical and is composed of five equally sized parts radiating out from a central axis. The inner shell, called a test, is made up of interlocking plates of calcium carbonate material and is covered by a thin skin and rows of spines (the classification “Echinoderm” derives from the Greek words for “spiny skin”). Spines vary in size and diameter according to species. An internal water vasculature system pumps water through the spines and tube feet, which are flexible tube-like structures that terminate with miniature suction cups. The internal organs are enclosed within the test, and the nervous system consists of a small nerve net encircling the mouth, from which five nerves enervate the rest of the animal. The mouth is found on the bottom, or oral face, of the animal. The sea urchin “jaw” consists of five bony teeth and tongue-like protrusion, collectively known as Aristotle’s lantern.

Sea urchins are benthic creatures and eat plant and animal matter, largely preferring kelp, algae, and sponges in their rocky habitats, as well as decaying matter that settle down from the water column. Sea urchins have a simple digestive tract encircled within the test. The anus is located at the aboral surface of the animal. The body cavity has an open circulatory system and is filled with coelomocytes. Coelomocytes perform essential clotting, scavenging and phagocytosis functions. Passive gas exchange in the coelomic fluid occurs through gill-like structures located around the mouth.

The gonads also reside within the body cavity and comprise a much as 30% of the body mass. The gonad of the sea urchin is the major reproductive and nutrient storage organ for the adult. The reproductive cycle is unique to each species (see Table 2), and is closely linked to photoperiod, water temperature, and food availability (reviewed in Pearse and Cameron, 1991). The gonad is made up of reproductive cells (oogonium, oocyte and ovum stages for females; spermatogonium, spermatocyte, spermatid and spermatozoon for males) as well as storage cells, also known as nutritive phagocytes (NPs). Various proteins, carbohydrates and lipids that are needed for gametogenesis and emergency metabolism are stored within the NPs. The percentage of NPs vs reproductive cells contributes significantly to the size and quality of the gonad, and varies throughout the reproductive cycle.

Reproductive Cycles

Despite the differences in spawning seasons for individual sea urchin species (Table 2), sea urchin reproductive cycles can be divided broadly into four stages (reviewed in Walker *et al.*, 2007; Pearse and Cameron, 1991). Stage I occurs immediately post-spawning (egg or sperm release) and lasts for about 3 months. Reproductive cells remain sparse at the beginning of Stage I, as NPs phagocytose unused egg and sperm precursors. The number of NP cells increases during this stage, yet reproductive cells eventually reemerge around the periphery of the gonads by the end of Stage I. In Stage II, which lasts 3–4 months, NP renewal continues and reproductive cells increase in number and size at the gonad periphery. By Stage III, the reproductive cells migrate into the gonad and continue to proliferate. This stage can last several months depending on the species, and the ratio of reproductive cells to NPs increases markedly during this time. At stage IV, gonads are packed full of differentiated gametes: eggs or sperm, whereas NP numbers are reduced or absent. Spawning occurs towards the end of Stage IV, in which most or all of the gametes are released. In the lab, this can be stimulated by 0.5 M KCl injection or by gentle shaking.

Fertilization and Early Cleavages of the Sea Urchin Embryo

Fertilization of Sea Urchin Eggs

The sea urchin is an excellent organism for live demonstration of fertilization and early development in lab or classroom settings (see Relevant Websites section). *In vitro* fertilization is easily conducted by mixing diluted eggs and sperm of the same species in sea

Fig. 1 Larval development of the sea urchin, *Lytechinus pictus*. Sea urchins were raised at room temperature. (A) Newly fertilized zygote; (B) 2-cell stage, 1.5 h post fertilization (hpf); (C) 4-cell stage, 2.5 hpf; (D) 8-cell composite image of two focal planes within an embryo, 3.5 hpf; (E) 16-cell stage, 4hpf; (F) 60-cell stage, 5hpf; (G) Early blastula before hatching from the fertilization envelope, 6.5 hpf; (H) Early gastrula, 24hpf; (I) Mid-stage gastrula, 26 hpf; (J) Prism larvae, 43.5hpf; (K) 4-arm pluteus larvae; (L) 8-arm stage; in a competent larvae, the rudiment that becomes the juvenile body begins to form around the region of the gut (yellow mass in the center of the embryo); in (M) the rudiment grows and the juvenile emerges from the larval body during metamorphosis; (N) Newly settled juvenile urchins are approximately 1 mm in diameter and form mouth parts to begin feeding on benthic diatoms and biofilms after 3 days. Later, their diet incorporates kelp and other macroalgae. Settlement of the juvenile takes approximately 4–5 weeks from fertilization. Scale bar = 50 μ m for (A)–(J). Scale bar = 0.25 mm for panels (K)–(M), and 0.5 mm for panel (N).

water. Given that sea urchin spawn externally, mechanisms exist to ensure species fidelity of the sperm and egg interaction. Sea urchin sperm contain a molecule known as bindin that is released during the acrosome reaction, and binds to vitelline layer of conspecific eggs. Evolution of this molecule is essential for the reproductive isolation of different species of sea urchin (Vacquier and Moy, 1977).

In the lab, when mature gametes are used at appropriate concentrations, successful fertilization routinely exceeds 95% of all eggs. Embryos develop through gastrulation within 2–3 days of fertilization, requiring nothing more than temperature-controlled sea water (Fig. 1). The feeding larval stage of the sea urchin, termed the pluteus larva, begins several days after fertilization and lasts from several weeks to months depending on species (Table 2). The rudiment, or juvenile sea urchin, develops indirectly within this larva and sheds the larval body upon settlement onto the substratum. The larvae and newly settled urchin juveniles feed on phytoplankton including microalgae and diatoms such as *Rhodomonas* and *Nitzschia*. Juveniles become gravid between 6 months and 2 years post-settlement, depending on the species.

Egg Activation and Surface Reorganization

Eggs of sea urchins are mature at release, having completed meiosis and arrested at the G1 phase of mitosis. Eggs are quiescent at spawning, but undergo a massive increase in metabolic activity at fertilization (reviewed in Pearse and Cameron, 1991). The initial signal for activation is a wave of calcium ions that sweeps across the egg, from the point of sperm fusion. Calcium release from intracellular stores is mediated by canonical second messengers, including the molecule cyclic ADP ribose (cADPR) which was discovered in sea urchins (Lee et al., 1989). These initial signaling events lead to a rapid change in membrane voltage from -70 to $+20$ mV, which acts as a fast block to fusion of other sperm with the egg (Jaffee, 1976). This is termed the fast block to polyspermy.

Following fertilization, dramatic cell surface reorganization involving sequential waves of vesicles insertion and membrane retrieval transforms the surface of the egg from one adapted to bind and fuse sperm to one adapted to promote development (reviewed in Vacquier, 1981). A conspicuous consequence of this reorganization is elevation of the fertilization envelope (Fig. 1(A)), which occurs within minutes of fertilization and is mediated by the exocytic release of 16,000 (in *S. purpuratus*) cortical granules docked at the egg surface. This envelope is formed by elevation of a glycoprotein meshwork under the plasma membrane termed the egg vitelline layer as proteins are released from the cortical granules (Vacquier et al., 1973). The resulting envelope is hardened by enzymes present in the cortical granules. This envelope acts as the slow block to polyspermy, and remains around the embryo until hatching thus likely also acting to protect against physical damage of the embryo.

The surface changes in the egg also include the activation of a several types of membrane transport activity including a Na^+/H^+ exchanger, amino acid transporters, and xenobiotic transporters. The exchanger alkalizes and activates the egg, while amino acid transporters concentrate nutrients from sea water into the egg (Epel, 1975). A notable surface change is an 80–100 fold increase in multidrug transporters activity by insertion of vesicles containing a homolog of mammalian P-glycoprotein (P-gp), the protein responsible for chemotherapeutic resistance of several types of cancer (Hamdoun et al., 2004). In early development, P-gp is responsible for effluxing environmental toxins and metabolic by-products from the embryo.

Early Cleavage Stages

An important feature of sea urchin embryonic development is the synchrony of development across embryos. As such, the early cleavage stages of sea urchins have been favorite models for the study of cell division. The mitotic apparatus was first isolated as

a structure in the sea urchin (Mazia and Dan, 1952), as were cyclins, which are cell cycle regulators that oscillate in abundance during the cell cycle and thereby regulate mitotic progression (Evans *et al.*, 1983). The duplication of the centrosome, which gives rise to the two poles of the mitotic apparatus and is the heart of the division apparatus of all eukaryotic cells, was first isolated from sea urchin zygotes (Thompson-Coffe *et al.*, 1996).

The first three cleavages of sea urchins are synchronous and symmetric. By the fourth cell cycle, cells at the vegetal pole of the embryo undergo two critical asymmetric cleavage events. The fourth cleavage produces four cells at the vegetal pole termed micromeres that eventually contribute to the larval skeleton. At the fifth cleavage, the micromeres divide once more to form four daughter cells termed the small micromeres. These small micromeres express canonical molecular markers of the germline (*vasa*, *nanos* and *piwi*) and are the presumptive primordial germ cells (PGCs), the embryonic precursors to the germline (Juliano *et al.*, 2006, 2010). Ablation of these cells results in formation of adults that are morphologically normal but lack egg or sperm (Yajima and Wessel, 2012).

Segregation of the Primordial Germ Cell Lineage

The germline lineage contributes to gametogenesis (the development of egg and sperm) in adult organisms. The location and developmental stage of PGC specification differs among species. For many animals, PGCs are specified by an inherited mechanism, in which determinants within the oocyte get partitioned into cells that subsequently acquire the germline fate. In contrast, an inductive signaling mechanism generates the germline in other animals. Sea urchins have a distinct embryonic segregation of PGCs. They appear to utilize an inherited mechanism of germline formation, whereby germline genes present in the egg are selectively retained only in the PGCs, and degraded elsewhere in the embryo (reviewed in Wessel *et al.*, 2014).

Sea urchin embryos form four PGCs (also termed small micromeres), at the vegetal pole at the fifth cleavage. The cells divide only once more in early development to form eight cells. The eight PGCs are motile cells capable of migration shortly after their formation, although they remain relatively stationary on the developing gut tube during gastrulation (Campanale *et al.*, 2014). At the end of gastrulation these cells home to the left and right coelomic pouches in a characteristic 5-left/3-right pattern (Pehrson and Cohen, 1986) (Fig. 2). The cells on the left seed the germline of the juvenile, while those on the right pouch undergo apoptosis. The evolutionary significance of this asymmetric germ cell segregation, and subsequent programmed death of the right fated cells, remains unclear. An intriguing hypothesis is that this serves as some PGC quality control mechanism.

The motility mechanisms for left-right segregation to the coelomic pouches are not yet well understood. It is hypothesized that the extended filopodia sense migratory cues, in the form of a morphogen or signaling gradient. In other animals, germline chemoattractants are derived from rhodopsin, CXCR4, or phospholipid signaling pathways. In the sea urchin system, the exact signals that home the PGCs have yet to be determined, although several transcription factors that operate in the left coelomic pouches (Materna *et al.*, 2013) have been implicated upstream of the homing signal (Martik and McClay, 2015).

An important aspect of PGC biology in all animals is that specification and migration occurs during a vulnerable window of inductive intercellular signaling and (re)programming. This requires a system that protects the cell from mutagens, as these could directly harm the next generation. Unexpectedly the protective transporters that are activated at fertilization are selectively reduced in the sea urchin primordial germ cells (Campanale and Hamdoun, 2012), suggesting a potential trade-off between signaling and protection pathways. The significance of this down-regulation is unclear, however it could be required for the detection of developmental signaling molecules. This phenomenon has been exploited to load sea urchin primordial germ cells with fluorescent dyes and isolate them to purity using flow cytometry (Swartz *et al.*, 2014).

Fig. 2 Migration of sea urchin primordial germ cells (PGCs) in *S. purpuratus*. The 8 PGCs (red) are located in a cluster at the tip of the developing gut tube (the archenteron) at the end of gastrulation (left inset). The PGCs at this stage are rounded, and maintain membrane (grey) contact with neighboring PGCs. Once migration is initiated the PGCs adopt an amoeboid shape and have short filopodia. In the final stage of migration the PGCs produce long filopodia and segregate into coelomic pouches on the left and right side of the archenteron (right most panel, right inset). Scale bar = 20 μ m.

Genetic and Cellular Control of Embryonic Development in Sea Urchins

Polarity and Establishment of the Major Body Axes

Both cellular and developmental manifestations of polarity are apparent in sea urchin eggs and early embryos. Purple sea urchin eggs have a polarized distribution of molecules that regulate axis formation along the animal-vegetal axis (A/V; i.e., top/bottom or future neural vs endomesoderm territories). In one species of urchin, *Paracentrotus lividus*, a reddish band of pigment granules is concentrated in the vegetal pole of embryo. In the purple sea urchin, the establishment of the A/V axis is initiated through β -catenin accumulation in the vegetal half of the egg (Wikramanayake *et al.*, 1998). Nuclearization of β -catenin and other maternal factors in the vegetal half of the developing embryo drives Delta/Notch signaling transduction. This initiates an endomesodermal program (future endoderm and mesoderm) in a ring of vegetal cells of the early embryo (Logan *et al.*, 1998; Davidson *et al.*, 2002). These include proteins in the *wnt* pathway, which are signaling pathways that turn on additional gene networks responsible for A/V axis formation. The secondary body axis, the oral-aboral (OA) axis (analogous to the dorsal-ventral axis), is established during cleavage stage by a maternal distribution of mitochondria (Coffman and Davidson, 2001). Downstream nodal signaling in the presumptive oral ectoderm further reinforces the OA axis (Lapraz *et al.*, 2015).

Cellular polarity, defined here as the segregation of membrane compartments to apical (outward facing) and basal (inward facing) compartments, is evident as early as the two-cell stage in sea urchins (Alford *et al.*, 2009). This polarity is also characterized by the segregation of thousands of membrane projections, known as microvilli, to the outward facing surfaces of the embryo. These microvilli are dynamic and grow and shrink with fertilization and the progression of the cell cycle (Schroeder, 1978). They appear to function in control of vesicle trafficking events and to increase the surface area of the embryo for absorption of nutrients from sea water. The individual cells of the embryo do not collectively form an epithelium until later in development when the blastocoel forms. At this stage (blastula) the embryo resembles a hollow ball of cells (Fig. 1(F)), with tight junctional complexes between cells and polarized distribution of membrane proteins to apical and basal surfaces.

Gene Regulatory Networks of Development

For scientists studying the flow of information from the nucleus, the sea urchin has long been an attractive model organism. Major advances in understanding or describing gene regulation of development, often for the first time, were pioneered in sea urchin embryos (reviewed in Ernst, 2011). Such discoveries include differential localization of DNA and RNA in the cell, maternal long-lived mRNAs present in the oocyte, functional separation of transcription and translation, and cytoplasmic polyadenylation of mRNAs (Table 1 and references therein). Indeed, the first eukaryotic genes to be cloned were histone genes from the sea urchin (Kedes *et al.*, 1975).

Studies in sea urchin embryos have generated exceptionally detailed descriptions of embryonic gene regulation and function. Reports in the 1970s and 1980s marked the birth of linking gene regulation definitively to developmental differentiation. By the 1990s and 2000s a “systems biology” approach to development – involving the generation of gene regulatory network (GRN) models – was established using the sea urchin (Davidson *et al.*, 2002). GRNs model hierarchical cell fate decisions by describing the interactions between transcription factors (TFs) and the promoters of their target genes. These cascades in gene regulation result in several layers of differentiation, from the initial patterning of major axes and body part plans, to the establishment of terminal cell-type specific differentiation batteries (reviewed in Davidson, 2010). The ability to selectively identify and perturb TF expression within the sea urchin embryo enabled the characterization of one of the most detailed gene expression analyses of any embryonic event described to date: endomesoderm specification (Davidson *et al.*, 2002). GRNs for other major developmental processes in the sea urchin have been characterized as well, including epithelial to mesenchymal transitions (EMT), biomineralization, coelomic pouch development and PGC homing, and muscle and immunocyte specification.

An active area of research in the sea urchin is devoted to linking the information encoded in the GRN to cellular events occurring during development. One example is EMT, a complex mix of changes in cell adhesion and migration that accompanies a cell's transition from an epithelial to mesenchymal phenotype. These events have been well-characterized at the GRN level in sea urchin primary mesenchyme (Saunders and McClay, 2014). In this context, distinct regulatory sub-circuits that involve at least thirteen different TFs work in parallel to initiate various EMT processes. These include remodeling of the basement membrane, apical constriction, epithelial de-adhesion, directed motility, loss of apical-basal polarity, and acquisition of mesenchymal adhesion and polarity.

Protection of the Sea Urchin Embryo From Pathogens and Environmental Stressors

Sea urchin embryos and larvae develop in the marine environment without maternal protection from environmental stressors. An integral aspect of development is protection of the germline and developing embryo from external mutagens or pathogens. Immune competence during development was first characterized in Echinoderm embryos in the late 1800s. Comparative embryologist Élie Metchnikoff observed wound healing and phagocytic behaviors in mesenchymal cells of sea star embryos. He documented the functional parallels between the Echinoderm phagocytes and vertebrate macrophages (Metchnikoff, 1893). In 1908, he was awarded the Nobel Prize in Physiology or Medicine for defining the “universality of phagocytosis”, a fundamental contribution to the field of

cellular immunology. Nearly a hundred years later, molecular biology has allowed for the characterization of immunocytes in the sea urchin larvae (and analogous adult coelomocytes) at the genetic level. The sequencing and assembly of the *S. purpuratus* genome identified an expanded innate gene repertoire (over 10-fold of that found in vertebrates), and illuminated the shared regulatory heritage of sea urchin and vertebrate immune systems (Hibino *et al.*, 2006; Rast *et al.*, 2006). These genes and TFs have now been mapped across adult and larval immune cell types and in responses to various pathogens (reviewed in Buckley and Rast, 2017).

Sea urchin embryos also express several hundred genes associated with xenobiotic metabolism (or the “chemical defensome”) in the first several days of development (Goldstone *et al.*, 2006). These include anti-oxidants, heat shock proteins, xenobiotic transporters and transcription factors that sense and respond to small molecules. The best studied of these defense pathways is the xenobiotic transporter system, including members of the ATP Binding Cassette (ABC) transporter and Solute Carrier (SLC) family. These transporters translocate a wide range of hydrophobic small molecules across membranes including xenobiotics and even signaling molecules. Sea urchin embryos have homologs of several human transporters responsible for chemotherapeutic resistance of cancer cells including ABCB1 (aka P-gp), ABCC1 (aka MRP1) and ABCG2 (aka BCRP). These genes are selectively regulated throughout embryonic and larval development, for either broad protective mechanisms, or for discrete functions in developmental signaling or morphogenesis (Shipp and Hamdoun, 2012).

Genome Manipulation and the Future of Sea Urchin Research

The unique biology and experimental advantages of the sea urchin mean that this animal will likely continue to serve an important role in developmental and reproductive biology research. Recent technological advances in gene editing are opening the door to the possibility of stable genetic manipulation as seen in fruit flies, mice and zebrafish. The ability to efficiently deliver molecules into the sea urchin embryo by microinjection has made it relatively easy to apply CRISPR-CAS gene editing systems to knockout genes in this embryo (Lin and Su, 2016). It is anticipated that these technologies will soon enable researchers to not only describe reproduction and development in this animal, but also to manipulate the genome across generations. This will prove valuable for the modeling of human disease pathways in the sea urchin, or for the development of new technologies to understand how the environment influences development.

Nomenclature

Bmp15	Bone morphogenetic protein 15	hpf	Hour post-fertilization
CRISPR/Cas9	Clustered regularly interspaced short palindromic repeats/CRISPR-associated protein-9 nuclease	HPG	Hypothalamic-pituitary-gonad
DHP	17 α , 20 β -dihydroxy-4-pregnen-3-one	LH	Luteinizing hormone
dpf	Day post-fertilization	LV	Late vitellogenic
EV	Early vitellogenic	mpf	Month post-fertilization
FG	Full-grown	MV	Mid-vitellogenic
FSH	Follicle-stimulating hormone	PG	Primary growth
Gdf9	Growth differentiation factor 9	PGC	Primordial germ cell
GnRH	Gonadotropin-releasing hormone	PV	Pre-vitellogenic
		SG	Secondary growth
		TALLEN	Transcription activator-like effector nuclease

Glossary

Apoptosis A process that kills a cell by genetic death program.

Cortical alveoli Special membrane-bound secretory structures in developing eggs that are located in egg cortex and involved in the cortical reaction during fertilization.

Fecundity Capability of reproduction indicated by number of eggs produced.

Fertilization The union of egg and sperm to form fertilized egg.

Genital ridge The structure in the embryo that develops into ovary or testis.

Germ cells Any cells that develop into eggs or sperm.

Gonochorist A species whose individuals have either ovary or testis.

Granulosa cell The somatic cells that surround oocytes or eggs to support their development.

Hermaphrodite An organism that has both ovary and testis in its lifespan.

Leydig cell The endocrine cells in the testis that are responsible for steroid production.

Oviposition The process of laying eggs.

Ovulation The process of releasing mature eggs from the follicles.

Pheromone Chemical signals from one individual that trigger responses in other individuals of the same species.

Primordial germ cells A special group of cells in early development that will develop into eggs or sperm.

Protogynous Change sex at certain time of life cycle from female to male.

Puberty The period during life cycle when an individual becomes sexually mature.

Sertoli cell The somatic cells that are closely associated with sperm cells to support their development.

Sex reversal Change of sex to the opposite one after sex differentiation.

Somatic cells Any cells of an organism that are not part of the germ cell lineage.

Spermatogonium Undifferentiated germ cells in the testis before entering meiosis.

Theca cell The endocrine cells of the ovarian follicle that are responsible for steroid production.

Toxicology Study of adverse effects of chemicals on living organisms and their mechanisms.

Vitellogenin A precursor protein that forms egg yolk.

Introduction

The zebrafish, *Danio rerio* (formerly *Brachydanio rerio*), is a small freshwater fish (<4 cm in standard body length from snout to the origin of the tail fin) native to South Asia including India, Bangladesh, Pakistan, Nepal and Myanmar, where it inhabits various waters, preferably shallow and still ponds, slow-moving streams, and even rice fields (Parichy, 2015; Spence *et al.*, 2008). Zebrafish was first recorded by Francis Hamilton in 1822, and it biologically belongs to the Family Cyprinidae of the Order Cypriniformes. The fish gets its name for its similarity to the zebra by having a few horizontal stripes on each side of the body. In its natural habitats, zebrafish prefers areas with overhanging vegetation and, as an omnivorous species, it feeds on a wide range of diet such as zooplankton, small insects, algae and other plant materials (Arunachalam *et al.*, 2013; Spence *et al.*, 2008). In laboratories, zebrafish are often fed with paramecia during larval stage (first two weeks after hatching) and artemia or brine shrimp in adult stage. Depending on conditions, the lifespan of zebrafish ranges from 3 to 5 years.

In the late 1960s, George Streisinger, who is considered the founding father of zebrafish research, first introduced this tiny slender fish as a vertebrate model for research on genetics and development at the University of Oregon. In the past 20 years, the zebrafish has gradually risen as one of the top model organisms for biological and biomedical research due to its biological advantages such as short generation time (2–3 months), high fecundity (~200 eggs/clutch), in vitro development, transparent embryos, and easy manipulation and maintenance. In addition, the susceptibility to many state-of-the-art cell and molecular biology techniques and amenability to chemical and genetic manipulations have contributed to its increasing popularity. Although the zebrafish was first developed as a model for developmental genetics, its utility has been quickly extended to many other fields of biological and biomedical sciences, including physiology, toxicology, disease modelling and drug development.

The zebrafish research has gained further momentum in recent years due to two major technological breakthroughs: (1) completion of its genome sequencing (Howe *et al.*, 2013) and (2) development of genome-editing technology (Gaj *et al.*, 2013). According to the genome sequencing data, the zebrafish shares 70% genes with humans and more than 84% of genes that cause human genetic diseases are present in the zebrafish, making it an excellent model for studying human gene functions, especially those that cause various human genetic diseases.

Zebrafish is well known to be highly prolific. In its natural habitats, zebrafish does exhibit clear seasonality in reproduction with the spawning season beginning right before the onset of monsoon (Spence *et al.*, 2008). However, under constant laboratory conditions, the domesticated zebrafish has lost such seasonality and it reproduces year-round every day or every few days. Each female zebrafish can produce hundreds of eggs per week. Such a high fecundity has made zebrafish an excellent model for studying reproduction as well as reproductive toxicology (Lawrence, 2011). This article reviews basic aspects of zebrafish reproduction and the major applications of this model in both basic and applied science.

Zebrafish Reproduction in Natural Habitats and Laboratories

Typically, the zebrafish becomes sexually mature around 3 months post-fertilization (mpf); however, this is highly variable, ranging from 2 to 6 mpf, depending on environmental condition, nutritional state and genetic background. It is not difficult to distinguish females and males in sexually mature zebrafish based on external appearance and morphology. The male zebrafish exhibit a slim shape with brownish coloration whereas the females display a more rounded body shape with silverish coloration. However, in juvenile zebrafish, it is very hard to identify males and females without dissection (Spence *et al.*, 2008). Studies have shown that the timing of sexual maturity is more related to body size rather than age (Chen and Ge, 2013). As a daily spawner, each female zebrafish can lay about 200 eggs on average per spawning, but the number can go up to 1000 eggs (our lab record is 800 per day). In its natural habitats, the zebrafish spawns in groups in early morning, and its spawning sites are normally shallow areas near the edge of waters, preferably with heavy vegetation (Laale, 1977). In laboratory settings, zebrafish spawn mostly within one hour after light is on in the morning. At 28°C, the embryonic development completes within 48–72 h post-fertilization (hpf). The newly hatched zebrafish larvae rely on the remaining yolk reserve for nutritional support, and they start to feed on zooplankton such as paramecia about 4 dpf.

Sex Determination and Differentiation

Like most other vertebrates and fish species, zebrafish is also gonochoristic in adults with individuals being either male or female. However, different from most other gonochoristic fish species such as medaka and salmonids whose gonads develop directly into ovaries or testes from undifferentiated state (differentiated gonochorists), the gonadal development of all zebrafish juveniles undergoes a special pseudo-female phase with non-functional ovary containing oocyte-like germ cells, which starts around 10–15 days post-fertilization (dpf). This phenomenon was first reported by Takahashi as “juvenile hermaphrodite” (Takahashi, 1977), and the fish is therefore considered a undifferentiated gonochorist. Sex determination and differentiation in the zebrafish occur later around 25 dpf with some individuals continuing female development pathway to become true functional females whereas others undergoing a process of sex reversal to become males (Maack and Segner, 2003). During sex reversal, the oocyte-like germ cells die through a process of programmed cell death or apoptosis (Uchida *et al.*, 2002). This gives way to the development of male germ cells from the germline stem cells. Because of this, zebrafish is also considered “juvenile protogynous hermaphrodite” (Fig. 1).

Similar to those of other animals, the germ cells originate at a distant location in the zebrafish embryos. To form the gonads, these early germ cells (primordial germ cells, PGCs) have to migrate a long distance, guided by both attractive and repulsive signals, to reach their final destination (genital ridges) at the dorsal side of the body cavity (coelom), where they will develop into either ovary or testis together with other somatic cells (Paksa and Raz, 2015). Unlike most gonochoristic fish species whose PGCs differentiate directly into either eggs or sperm in females and males respectively without sex reversal, zebrafish undergoes a special period of juvenile females followed by further differentiation into males and females. Unlike mammals and some fish species such as medaka and tilapia with sex-determining genes, the mechanism that determines the direction of gonadal development (ovary or testis) remains entirely unknown in the zebrafish. It is generally accepted that instead of having single sex-determining gene, the sex of zebrafish is determined by multiple genes (polygenic hypothesis) (Liew *et al.*, 2012).

Fig. 1 Schematic illustration of zebrafish gonadal differentiation. All juveniles of zebrafish undergo a special pseudo-female phase with non-functional ovaries. In about half of individuals, the oocyte-like germ cells continue to grow to become functional oocytes in the ovary of females; whereas in the other half individuals, the germ cells die through a special process called apoptosis while the stromal cells proliferate to fill up the space between the dying oocytes. Among the stromal cells are spermatogonial stem cells that will develop into spermatogenic cells of different stages in a cystic manner.

Control of Zebrafish Puberty Onset

Once after sex differentiation is completed, the zebrafish will stay in immature juvenile stage for a short while before becoming sexually mature at puberty, which is a critical period when an animal becomes sexually mature and attains reproductive capacity. In female zebrafish, the initiation of puberty or puberty onset is marked by the ovarian follicles that start to accumulate a special structure called cortical vesicles/alveoli in the oocytes (Chen and Ge, 2013; Taranger *et al.*, 2010). These follicles are staged as pre-vitellogenic (PV) or stage II. Interestingly, the timing of puberty in the zebrafish seems related to the body size rather than age, and the body weight and standard length of female zebrafish are 100 mg and 1.8 cm respectively when puberty starts around 45 dpf under optimal environmental conditions (Chen and Ge, 2013). After puberty onset, the ovarian follicles undergo fast vitellogenic growth to reach sexual maturity, and the fish may start spawning as early as 60 dpf (our laboratory), when the standard length reaches about 2.3 cm (Lawrence, 2011; Spence *et al.*, 2008).

Although the mechanism by which body growth influences zebrafish reproduction remains largely unknown, it has been generally believed that the puberty onset in the zebrafish is controlled by neuroendocrine signals from the hypothalamus (brain), in particular the kisspeptin-gonadotropin-releasing hormone (GnRH) pathway (Servili *et al.*, 2011). This pathway is well known in mammals to be responsible for initiating puberty, and numerous studies in fish models including the zebrafish have also pointed to the involvement of this pathway in puberty onset. However, recent studies using the state-of-the-art genome-editing technology do not support this concept in the zebrafish (see below).

Regulation of Zebrafish Reproduction

After puberty onset, both males and females will embark on a continual process of gamete production, viz. oogenesis/folliculogenesis in females and spermatogenesis in males. The maturation and function of the zebrafish reproductive system are controlled by the hypothalamic-pituitary-gonad (HPG) axis in both males and females. Similar to that in other vertebrates, the zebrafish HPG axis is believed to be governed by the master neuropeptide from the hypothalamus, i.e., GnRH, which acts at the pituitary to control the production and secretion of gonadotropins, viz. follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Both FSH and LH are released into the blood and circulated to the gonads, ovary in females and testis in males, where they control all aspects of gonadal functions, including production of gametes (eggs and sperm) and sex steroid hormones.

Recent genetic studies using gene knockout approach have shown that FSH is essential in controlling early stage of gonadal development in both males and females whereas LH is responsible for the final maturation and release of eggs in females (Zhang *et al.*, 2015b). Like their counterparts in mammals, zebrafish FSH and LH also signal through specific receptors on the membrane of gonadal cells. However, in addition to its cognate receptor Lhcgr, zebrafish LH can also activate FSH receptor Fshr to some extent (So *et al.*, 2005). The unique LH-Fshr pathway has recently been demonstrated to play an essential role in rescuing the phenotype of FSH loss (Zhang *et al.*, 2015b). In addition to pituitary gonadotropins and gonadal steroids, the regulation of reproduction also involves various peptide growth factors that work mostly as paracrine factors at different levels of the axis (Ge, 2005).

Female Reproduction

Like that in other animals, ovary plays a central role in female zebrafish reproduction. Different from other organ systems, the ovary in the zebrafish or any fish in general is the most dynamic organ that undergoes dramatic changes in both size and function during the reproductive lifespan. The basic structural and functional units in the ovary are follicles. Based on the size and morphology, the growing zebrafish follicles can be divided into two major phases: primary growth (PG, also called stage I; < 150 μm) and secondary growth (SG). The SG phase can be further divided into several stages: pre-vitellogenic (PV, or stage II; ~ 250 μm), early vitellogenic (EV, or early stage III; ~ 350 μm), mid-vitellogenic (MV, or mid-stage III; ~ 450 μm), late vitellogenic (LV, or late stage III; ~ 550 μm), and full-grown (FG; ~ 650 μm) (Selman *et al.*, 1993; Zhou *et al.*, 2011). During SG phase or vitellogenic growth, the oocytes absorb large amount of yolk proteins (vitellogenin) produced in the liver, and these proteins are converted and deposited in the oocytes as yolk granules, which serve as the nutritional reserve to support embryonic development after fertilization.

Each follicle consists of a centrally-located oocyte and a surrounding layer of somatic follicle cells. There are two types of cells that form the follicle layer, the granulosa and theca cells. The granulosa cells form the avascular inner layer that has direct contact with the oocyte whereas the theca cells are located outside with rich blood supply. These two types of cells are physically separated by a layer of amorphous basement membrane, and they perform distinct functions during follicle growth or folliculogenesis (Ge, 2010). Different from their counterparts in mammals where the follicles consist of multiple layers of granulosa and theca cells, there is only one monolayer of granulosa and theca cells each in the zebrafish follicle. The granulosa cells have direct contact with the oocyte to support and regulate its development whereas the theca cells are the major steroidogenic cells that produce steroid hormones. Evidence has been increasing that the oocyte and outside somatic cells (granulosa and theca) work closely in the ovary to drive follicle development. It is now generally believed that the somatic follicle cells are the site where various external endocrine hormones work to regulate follicle development, e.g., pituitary FSH and LH. However, the germ cell oocyte also plays an important role by releasing various biologically active factors, mostly peptide growth factors, to influence follicle cell functions, such as growth differentiation factor 9 (Gdf9) and bone morphogenetic protein 15 (Bmp15). Various regulatory factors from the oocyte and follicle cells therefore form an intrinsic network of communication within the follicle to orchestrate follicle development (Ge, 2005).

Upon completion of follicle growth, the full-grown (FG) follicles will undergo a process of final maturation followed by release of mature eggs (ovulation) for fertilization. Numerous factors have been reported to participate in controlling this critical final event, including pituitary gonadotropin LH, steroid hormone progesterone (17α , 20β -dihydroxy-4-pregnen-3-one; DHP) and local growth factors such as activin, epidermal growth factor (Egf), and insulin-like growth factor 3 (Igf3). Recent studies using state-of-the-art genome editing technologies have provided unequivocal evidence for the importance of some of these factors in regulating final oocyte maturation and ovulation.

Male Reproduction

Like the ovary in females, the testis is the central player in male reproduction in the zebrafish. Similar to those of other vertebrates, the zebrafish testis also consists of seminiferous tubules where sperm development or spermatogenesis occurs. In addition to the germ cells, testis also contains two types of somatic cells that are essential for male function; they are the Sertoli cells located within the tubular compartment together with the germ cells and the Leydig cells located outside the tubules or interstitial space. Similar to situation in the ovary, the two types of somatic cells are separated by a basement membrane (Schulz *et al.*, 2010). The Sertoli and Leydig cells in the testis are functionally equivalent to the granulosa and theca cells in the ovary respectively in that the former are in physical contact with the developing sperm cells without blood supply and the latter are richly supplied by blood and are responsible for production of male sex steroid hormones.

Like other fish species, the zebrafish testis belongs to the cystic type. In the tubular compartment, the germinal epithelium contains numerous cysts of different sizes and developmental stages, and each cyst consists of a clone of germ cells surrounded by the Sertoli cell extensions. Each clone originates from a single spermatogonium and the development of all cells within a clone or cyst is synchronous. The cystic type of spermatogenesis makes identification of different developmental stages a lot easier as compared to the non-cystic type seen in higher vertebrates. In the zebrafish testis, the production of sperm or spermatogenesis is divided into three stages: the mitotic stage of spermatogonial proliferation, the meiotic stage of spermatocytes (primary and secondary), and the spermatogenic stage of final maturation into motile spermatozoa. Like folliculogenesis in the ovary, the

spermatogenesis in the testis is also tightly controlled by both endocrine hormones such as FSH and LH from the pituitary, local regulatory factors such as anti-Müllerian hormone (Amh) and Igf3, as well as steroid hormones (Schulz *et al.*, 2010).

Reproductive Behavior

After production of gametes (eggs in females and sperm in males), the successful reproduction depends on appropriate spawning behavior to ensure fertilization. In laboratory condition, the zebrafish spawns continuously on daily basis or at intervals of a few days. The trigger for spawning behavior is well known to be lighting after darkness. Upon light-on, the male and female zebrafish perform spawning behavior that results in release of mature eggs and sperm for fertilization in water. The process of spawning normally lasts for about one hour after light on. In its natural habitats, zebrafish spawning occurs at dawn, also depending on photoperiod.

During spawning, the males display an aggressive chasing behavior to pursue females with an attempt to lead the females to the spawning sites. In both laboratory condition and natural habitats, zebrafish prefer shallow areas with gravel substrate, preferably with vegetation. At spawning sites, the male would position itself closely to the side of the female so that their genital pores are well aligned. This behavior triggers the release of eggs by the female (oviposition) and sperm by the male for fertilization (Spence *et al.*, 2008).

The courtship behavior displayed by males is thought to be induced by pheromones (olfactory cues) released by females. Waterborne pheromones are perceived by olfaction and important for aquatic animals to communicate for individual recognition and synchronization of reproductive behavior. Exposure to pheromones from one sex may trigger responses of the endocrine system in the opposite sex, which influences sexual maturity and reproductive success. Studies have shown that male zebrafish can release chemical cues to stimulate female ovulation (van Den Hurk *et al.*, 1987) whereas pheromones from females activate males while suppress the reproductive performance of other females (Gerlach, 2006). The exact chemical identities of zebrafish pheromones remain unclear, and early studies have implicated potential roles for steroid glucuronides in pheromonal communication in both male and female zebrafish (van den Hurk and Lambert, 1983; van Den Hurk *et al.*, 1987).

Zebrafish as a Model for Reproductive Endocrine Disruptors

In the past decade, the zebrafish has not only emerged as a model species of choice for basic study on fish reproduction, but also become popular as a model for studying reproductive toxicity of environmental pollutants, especially those with endocrine-disrupting activities. Endocrine-disrupting chemicals (EDCs) refer to the compounds, either natural or synthetic, that interfere with the function of the endocrine system in wildlife and humans. The zebrafish has been used for screening compounds, evaluating effects, and understanding action mechanisms (Segner, 2009). The polygenic sex determination and high plasticity of sex differentiation make zebrafish particularly susceptible to external and internal conditions or factors that may influence reproduction, therefore providing a unique model for assessing materials that may disrupt reproductive development and function. Our knowledge of zebrafish reproduction has provided a foundation for establishing endpoints of assays, identification of biomarkers, experimental design and data interpretation.

As a vertebrate species, the zebrafish is close to humans in many aspects of body functions. The endocrine system of the zebrafish is very similar to that of humans. Therefore, the information obtained from the zebrafish model on EDCs will be more relevant to human health than invertebrate models. The high fecundity (~200 eggs per spawning), in vitro and fast embryonic development (72 h), and short generation time (~3 months) all make zebrafish a superior model as compared to the rodents. Furthermore, numerous mutant zebrafish lines have been established, and these mutants will be valuable tools for dissecting and understanding the action mechanisms of various EDCs (Segner, 2009).

Several approaches can be used with the zebrafish model to assess EDCs. First, a specific marker molecule that responds to a particular endocrine pathway can be used to monitor the effects of EDCs on specific endocrine axes, e.g., vitellogenin expression in the liver in response to exposure to estrogenic substances. Second, without targeting any particular pathways, a more global approach, i.e., transcriptomics, will provide comprehensive information on which endocrine pathways are affected. Third, since gonads are the ultimate organs of the reproductive system, histopathological analysis of gonadal development and maturation as compared with the control will reveal the impacts of EDCs on the overall functionality of the HPG axis. Forth, transgenic zebrafish lines that carry reporter genes such as green fluorescent protein (GFP) whose expression is controlled by specific endocrine-responsive promoters can be useful for live monitoring of EDCs in water.

Zebrafish as a Genetic Model for Vertebrate Reproduction

Although zebrafish has been a popular model for developmental biology using reverse genetics approach, the major tool used was morpholino-mediated gene knockdown. Since gene knockdown does not involve gene deletion from the genome and it works only for a short period of time (<5 dpf), the study of zebrafish reproduction by reverse genetics had been hindered. However, this situation has quickly changed in recent years with the new generation of gene knockout tools available to non-rodent species, in

particular TALEN and CRISPR/Cas9. Using these tools, a variety of functional genes in the zebrafish HPG axis have been disrupted for functional assessment. Phenotype analysis of these mutant zebrafish lines has confirmed some well-accepted concepts regarding fish reproductive axis and its control, but also revealed novel aspects of gene functions that would be difficult to demonstrate without using these genome-editing technologies. In this wave of technological revolution, zebrafish has become one of the top models for testing and evaluating the efficacy of various protocols.

It is generally believed that the HPG axis in fish is similar to that of mammals in terms of organization and function. The hypothalamus produces and releases a master neuropeptide, GnRH, which controls biosynthesis and secretion of gonadotropins (FSH and LH) from the pituitary. GnRH in turn is subject to regulation by another neuropeptide kisspeptin in the hypothalamus. The gonads, in response to FSH and LH, produce sex steroids including estrogens in females, which are produced by the action of aromatase, an enzyme that converts androgens to estrogens. Using gene targeting technology, these important functional genes in the axis have been evaluated for their roles and importance in the zebrafish.

As expected, the deletion of the gene coding for FSH β (*fshb*) significantly delayed puberty onset in both males and females although the mutant fish was fertile in the end because of the rescue of FSH function by LH, which can activate FSH receptor (*Fshr/fshr*). On the other hand, the loss of LH by deleting LH β gene (*lhb*) had no effect on gonadal growth in both males and females, but the female mutant was infertile due to failed oocyte maturation and ovulation (Zhang *et al.*, 2015b). Interestingly, disruption of *fshr* gene resulted in severe retardation of ovarian development and sex reversal to males whereas the loss of LH receptor (*Lhcgr/lhcgr*) displayed no phenotype (Zhang *et al.*, 2015a). This discovery would be extremely difficult to make without the genome-editing technology. Estrogens have long been believed to play important roles in gonadal differentiation in fish. This view is fully supported by deleting the ovarian aromatase gene (*cyp19a1a*) in the zebrafish. As expected, the loss of *cyp19a1a* resulted in an all-male phenotype with no females in the mutants (Lau *et al.*, 2016). A surprising discovery concerns the role of hypothalamic kisspeptin-GnRH pathway in zebrafish reproduction. Deleting kisspeptin genes (*kiss1* and *kiss2*) and its receptors (*kissr1* and *kissr2*) in the zebrafish caused no abnormality in reproduction for both males and females (Tang *et al.*, 2015), and this is supported by a separate study demonstrating that the loss of GnRH gene (*gnrh3*) also had no effect on reproduction in both males and females (Spicer *et al.*, 2016).

The powerful genome-editing technology has provided an unprecedented tool for scientists to explore the regulatory network of the reproductive axis. Although many results support the traditional views about the roles and importance of different functional genes in the axis, some results have provided information totally beyond the current concepts. With its technical and biological advantages, especially amenability to genetic manipulation, it is conceivable that zebrafish will be a dominant model for genetic analysis of reproductive functions in fish.

Summary

In the past 20 years, there has been a substantial growth of studies on zebrafish reproduction in both males and females. Our understanding of zebrafish reproduction now covers a wide range of topics including primordial germ cell development, sex/gonadal differentiation, folliculogenesis/oogenesis in the ovary, spermatogenesis in the testis, and spawning behavior and reproductive success. This knowledge has increased the popularity of zebrafish as a model in other areas including environmental science for evaluating man-made and natural compounds that may interfere with normal reproduction. Recent emergence of the genome-editing technology and its successful application in the zebrafish will further strengthen the status of this tiny fish as a model organism for studying fish as well as vertebrate reproduction (Fig. 1).

Glossary

Blastocyst The blastocyst is a structure formed in the early development of mammals after fertilization of an ovulated egg. There is an inner cell mass which forms the embryo (and is the source of embryonic stem cells). The outer layer of the blastocyst consists of cells called the trophoblast. This layer surrounds the inner cell mass and a fluid-filled cavity known as the blastocoele. The trophoblast gives rise to the placenta.

Chimerism or chimera (also spelled chimaera) A mouse or rat composed of cells from different zygotes. Animal chimeras are produced by coupling multiple fertilized eggs in one embryo which can result in two blood types, male and female organs in the same animal or other variations.

Hemodichorial placenta Approximately two layers of tissue separating the fetal and maternal blood flow.

Hemotrichorial placenta: simplistic

definition Approximately three layers of tissue separating the fetal and maternal blood flow.

Intramuscular Referring to injection of material directly into the muscle layers.

Mosaicism Inclusion of two different sets of genes in one individual.

Pheromones Chemicals produced by an organism that transmits a message to other members of the same species.

Photoperiod The number of hours of light to the number of hours of darkness.

Puberty The onset of sexual maturity and ability to bear young. Puberty occurs before full body size and weight are obtained and is not an ideal time to breed for the first time.

Subcutaneous Referring to injection of material into the space between the skin and underlying muscle layers.

Transgenic animals Strains of animals produced by genetic manipulation – includes “knock-out” animals (a strand of DNA deleted) or “knock-in” animals (a strand of DNA added). These strains are developed then stabilized by strategic breeding strategies.

Triploidy Chromosome abnormalities in which an extra set of chromosomes is included into the fetus genetic material.

Wild type animals Wild type animals have had no genetic manipulation and may be considered equivalent to “out-bred” or “random source” animals.

Introduction

This article is to present an overview of laboratory rat (*Rattus rattus*) and mouse (*Mus musculus*) reproduction. Mice have 40 chromosomes, while the rat has 42. Rats and mice do not breed naturally with each other and attempts to merge rat and mouse DNA into eggs (to develop chimeric animals) has not been successful. When working with both species, appreciating the similarity and differences between these two species can be very helpful.

Because of the many genetic strains of mice and rats that are available, the reproductive data such as length of gestation, age at puberty or number of pups/litter is variable. Average numbers are used in this article but successful breeding is always dependent on knowledge of the reproductive tendencies of the strain of interest. For example, androgenic knock-out male mice show decreased reproductive performance due to anatomical changes in the penis anatomy compared to wild type animals (Yang *et al.*, 2010). Some strains of hairless rats tend to be poor mothers as they produce little to no milk (Sharp and Vilano, 2013). New transgenic lines always need to be monitored carefully for reproductive abilities since the many genes which drive reproductive success can be altered in unexpected ways by targeted genetic alterations.

Anatomy

Reproductive anatomy of rats and mice is basically similar to all mammals and in depth discussions are easily found (Jacoby *et al.*, 1984; Kohn and Clifford, 1984). A few significant points are discussed below (Table 1).

Female Rats and Mice

Cervical Anatomy

The literature often describes rats and mice as possessing two cervixes which is incorrect. Rats have two separate cervixes, one in each uterine horn, which unite at the vagina. The mouse uterine horns unite into an externally undivided uterine body with cranial and caudal internal parts. Internally the uterine body has two lumen separated by a midline septum which are sometimes labelled as paired cervixes. However, the two lumens join in into one narrowed, tapered canal which forms the uterine neck or cervix of the

Table 1 Similarities/Differences between rat and mouse reproductive anatomy

<i>Anatomy</i>	<i>Rat</i>	<i>Mouse</i>
Mammary glands	Six pairs	Five pairs
Cervix	Two cervix	One cervix
Clitoral glands	Connect to urethra	Variable connection to urethra depending on strain
Ovaries, Oviducts, Uterine Horns	Two	Two
Neonate vaginal anatomy	Vaginal plate	No vaginal plate
Male accessory glands	Seminal vesicles, prostate gland of which the anterior lobe is considered the coagulating gland, bulbourethral (Cowper's) glands, ampullary glands, and preputial glands	The same as the rat

mouse which then projects into the vagina ([Leppi, 1964](#); [Hamilton, 1947](#)). Technically, the mouse has one cervix while rats have two.

Exocrine Glands

Clitoral exocrine glands are present in both species which secrete sebaceous pheromones, very important to the sex life of mice (apparently not such a big deal for rats!). The clitoris of rats connects directly to the urethra while the mouse clitoris may be completely separate from the urethra or may be partially connected, depending on the strain of the mouse ([Yang et al., 2010](#)).

Mammary Tissue

Female rats have six pairs of mammary glands, while mice have five pairs. Mammary gland tissue is extensive, extending from the nipples up along the sides and flanks of the animal towards the back and the sides of the neck. Older rats and mice can develop mammary tumors in unusual areas, such as the flanks or neck.

Male Rats and Mice

Inguinal Canal

The inguinal canals remain open throughout the animal's life and testicles may be retracted into the abdomen. A large fat pad exists which tends to prevent inguinal hernias secondary to castration, however it is recommended to close the inguinal canal when performing castration.

Accessory Glands

Rats and mice possess seminal vesicles, coagulating glands (which may be part of the prostate), prostate glands, ampullary glands and preputial glands. Secretions from the coagulating gland and seminal vesicles make up most of the plug that is deposited after coitus. The preputial and ampullary glands are not found in humans and are a source of pheromones.

Determining Gender

Male Rats and Mice

Male adult animals show distinct scrotums with visible penises. Sometimes the testes may be retracted into the inguinal canal. Hold the animal vertically (head up) to allow the testes to slide into the scrotum and become visible.

Female Rats and Mice

Female mice and rats show a shorter anal – genital distance than males but sometimes the genital opening can be confused with a penis, especially in very young animals. Prominent rows of nipples start to become visible at 8–9 days of age in females of both species.

Pre-Pubertal Animals

To determine gender it is easiest to compare ano-genital distances of new born animals. Males tend to be about 1.5–2X greater distance than females. In male mice there may be a dark pigmentation visible in the pre-scrotal region. Pale undescended testes

Fig. 1 Gender identification of neonatal mice.

may be visualized through the abdominal wall of mice. As neonates age, it can become harder to differentiate gender until 8–10 days of age when nipples appear on females. At 18–28 days (weaning), the male penis is more recognizable ([Fig. 1](#)).

Puberty

Puberty begins as Follicle Stimulating Hormone (FSH) promotes egg, sperm and hormone production leading to the animals becoming capable of reproducing. Age of onset of puberty varies between strains. For example, the C3H/HeOJ mouse begin successful mating at about 6 weeks old, where BALB/cJ mice wait until about 8 weeks of age ([Silver, 2008](#)). But puberty can begin as early as 30 days and genders should be separated to prevent uncontrolled mating. It is best to allow the animal to mature before allowing breeding.

Males

Mature sperm has been reported as early as 30–35 days of age ([Sharp and Vilano, 2013](#)) with most sources reporting best fertility beginning about 5010 days. If a male is still a virgin at 2.5–3 months, he will not plug well (create a vaginal plug after mating) and is less likely to be a prolific breeder ([Burds Connor, 2007](#)).

Females

Though some female rats and mice may ovulate as early as 28–30 days of age, most animals first ovulate naturally around 6–8 weeks of age. Both species require the vagina to open before they can be bred. Female rats have a vaginal plate which must degenerate prior to vaginal opening. (For more details, see [Kohn and Clifford \(1984\)](#) or [Del Vecchio \(1992\)](#)). In mice, exposure to adult males or their urine can bring on earlier ovulation; exposure to mature females or their urine may delay the initial ovulations. A female will produce best over her lifetime if she is allowed to obtain most of her body growth before breeding. Once paired with a mate, a litter should be successfully produced in less than 2 months. The number of litters per female mouse can vary per strain – for example, the average number of litters is 2.2 per AKR/J females compared to 4.8 in FVB/N strains ([Burds Connor, 2007](#)).

Reproductive Cycles

Estrous

Both rats and mice are continuously polyestrous and ovulate spontaneously. The entire cycle of four stages (proestrus, estrus, metestrus, diestrus) is approximately 4–5 days long in both species ([Marcondes et al., 2002](#)). Knowing where a female animal is in her cycle enables coordination of pup production or embryo transfer. The stages are identified by characteristic cellular changes in microscopic exams of vaginal smears and are well described (see [Fig. 2](#)). Rats tend to ovulate later in their cycle than mice ([Table 2](#)).

Cycle regularity is generally stable in adult animals but may be disrupted. Rats exposed to 24 h light tend to develop persistent estrus and cystic ovaries ([Sharp and Vilano, 2013](#)) while chronic low light exposure during dark cycles causes earlier vaginal opening and ovarian atrophy ([Fox and Laird, 1970](#)). Exposure to estrogenic substances in feeds or plastic housing may affect cycling regularity. The cycles become more irregular in older animals. Pheromones play an important role, more in mice than in rats, and can be manipulated for timed breeding.

Table 2 General characteristics of reproductive cycles in mice and rats

	Mouse ^a (unless marked)	Rat ^b (unless marked)
Sexual maturity	45–65 days ^a	50–75 days ^a
Puberty	28–49 days	Variation reported – 50–72 days males Females as early as 35 days ^a
Vaginal Opening (days)	24–28	28–60
Recommended first mating	6–8 wks ^a	65–110 d ^d
First mating wt male (gm)	20–30 ^d	300 ^d
First mating wt female (gm)	20–30 ^d	250 ^d
Estrus length	6–8 h	20 h
Post partum Estrus (Hours)	14–24, fertile	3–18 h, fertile
Gestation (d)	19–21 ^a	21–23 ^a
Duration of pup delivery	2 h ^a	15–30 min ^a
Litter Size (pups)	6–12 ^a	3–18 ^a
Birth weight	0.75–2.0 gm	5–6 gm
Eyes open (d)	12–14	10–12
Able to hear	10 ^c	9 ^c
Weaning (d)	21–28d	20–21
Eating solid food (d)	14–16 ^c	11–14 ^c
Breeding lifespan	210–270 days ^a	350–440d ^a

^aMay vary with strain.^bSharp, P., Vilano, J., 2013. The Laboratory Rat, second ed. A volume in the Laboratory Animal Pocket Reference Series. (Eds.), Laboratory Animal Medicine, American College of Laboratory Animal Medicine Series, second ed. San Diego, CA: Academic Press, pp. 40–52.

Timing of Ovulation

Ovulation in mice usually occurs during the dark period about 2–3 h after the onset of estrus (though there may be cycles without ovulation). Rats tend to ovulate during the metestrus period (Sharp and Vilano, 2013)] about 8–11 h after the onset of estrus and usually between midnight and 2 am (Peluso, 1992). Ova remain viable about 10–12 h after ovulation (Fox and Laird, 1970). Rats and mice both have fertile post-partum estrus.

Physical Changes Associated With the Cycle

In female mice, the opening of the vaginal orifice becomes more evident and the vulvar tissue swells during proestrus and estrus. The changes can be visible to the experienced eye (see Fig. 2). Female rats in estrus will exhibit characteristic behavior: ear quivering when the back or head are stroked and lordosis (a “sway-back” posture) when the pelvic area is stimulated. Rat vulvar tissue may swell and the vaginal wall appears dry (due to thickening of the tissues). The rat vaginal wall area is moist during metestrus and diestrus.

Determining Stage of Cycle

Vaginal cytology is used to determine the stage of an animal’s cycle. Methods to obtain cells for analysis are well described (Bronson *et al.*, 1996; Soleberg, 2004) and multiple videos are available on Youtube. Vaginal wall cells can be gently collected and then microscopically examined. Presence and proportions of epithelial cells with nuclei, cells with no nuclei (“cornified”), leukocytes and bacteria can be evaluated to identify the cycle stage. (see Fig. 3).

As shown by Koto *et al.* (1987), measurement of electrical impedance of the vagina may also be used to determine the stage of the cycle in female rats. The correlation of the changes with hormonal changes is not exactly the same for every strain but is consistent within strains – correlations must be established for each strain for the procedure to be predictive.

Pseudopregnancy

Pseudopregnancy, a condition resembling pregnancy that is marked by a persistent corpus luteum and no pups, is purposefully induced during embryo transfer procedures to produce recipient mice (see below). Vaginal stimulation of an animal near or in estrus or mating with an infertile (exhausted, vasectomized or poor breeder) male will induce pseudopregnancy. The condition may also be induced by manipulating pheromones in mice. Pseudopregnancy may last 13 days or longer in some strains of mice and rats.

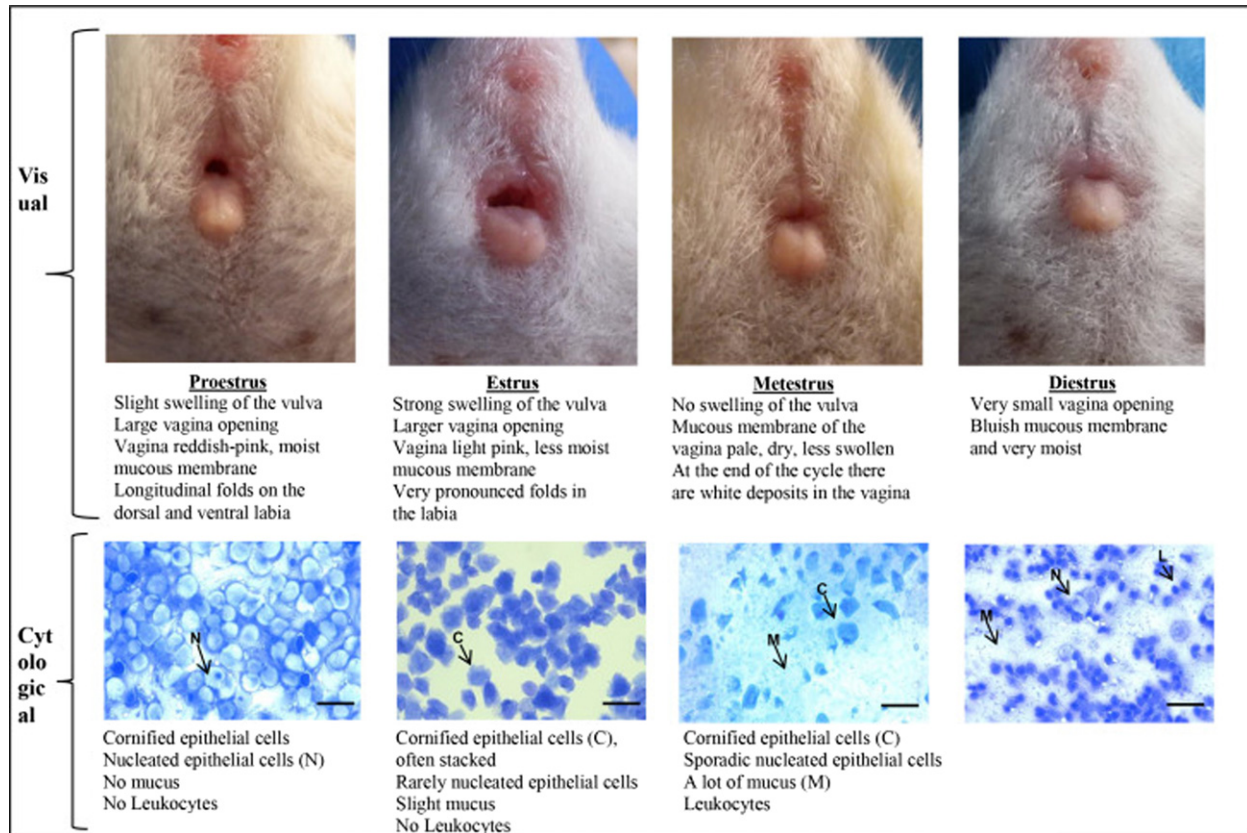

Fig. 2 Characteristics of vaginal smears and external changes. Reproduced from Heykants, M., Mahabir, E., 2016. Estrous cycle staging before mating led to increased efficiency in the production of pseudopregnant recipients without negatively affecting embryo transfer in mice. *Theriogenology* 85 (5), 813–821.

Breeding

Consistent husbandry of breeding animals and knowledge of the strain's reproductive tendencies are important in any successful breeding system. Consistent photoperiod is crucial to regular cycling (as discussed above). Caloric restriction may cause total cessation of estrous cycles and delay sexual maturity. High ambient temperatures (above 26.6 °C) can result in male infertility, causing irreversible degeneration of seminiferous epithelium (Pucak *et al.*, 1977) while cooler temperatures may lead to chilling and loss of pups.

Cycling can be irregular in young females but tends to stabilize at about 50–60 days of age. Aging female rats are considered “reproductively senescent” by about 10–12 months (Sharp and Vilano, 2013). Mice are usually retired from 6 months to one year of age depending on strain (Fox *et al.*, 1984). As animals age, their eggs show higher frequencies of genetic abnormalities such as triploidy and mosaicism in blastocytes recovered after superovulation (Shaver and Martin-DeLeon, 1975; Del Vecchio, 1992).

Copulation and Fertilization

Rats and mice perform coitus during the dark phase of the photoperiod. If the light cycle is reversed, the behavior will reverse as well (Jacoby *et al.*, 1984). Male activity is described by Dewsbury (1970). Again, activity is strain dependent. For example, recovery of libido occurs in about one hour in DBA mice but may take up to four days in B6 mice (Silver, 1995).

Plugging

Mating is confirmed when a visible vaginal plug is observed in the vagina or on the cage floor. The plug is formed by secretions of the vesicular and coagulating glands of the male following copulation, and extends from the vulva to the cervix. Pregnancy is rare if the plug is not observed, but the presence of the plug does not guarantee pregnancy.

When a plug is observed, the next day is considered day #1 of pregnancy (if the mating was fertile). To observe a plug, the animal is gently lifted by the tail and the vagina inspected. The plug is deeper in the mouse and often the vulvar lips need to be

Fig. 3 Mouse Estrous Cycle Identification Tool. Reproduced from Byers, S.L., Wiles, M.V., Dunn, S.L., Taf, R.A., 2012. Mouse Estrous Cycle Identification Tool and Images. Open access article: <http://journals.plos.org/plosone/article?id=10.1371/journal.pone.0035538> PLoS One 7 (4): e35538.

gently spread with a cotton swab or a dull probe to facilitate viewing. Plugs tend to dislodge after 12–24 h so it is best to look for them right away in the morning. The combination of plug observation and vaginal cytology will determine where an animal is in the reproductive cycle.

Fertilization

Fertilization usually occurs in the ampulla or upper portion of the oviduct in mice. The ova can be fertilized up to 10–12 h after ovulation. The blastocyst implants into the endometrium within 4–7 days after post-coitus. For a detailed description of implantation, apposition, attachment and invagination processes, see [Lee and DeMayo \(2004\)](#).

Implantation

Mice and rats experience delays in implantation. This delay appears to be at least partially controlled by quiescent uterine stromal cells which cause the embryos in the blastocyst state to remain dormant ([Lee and DeMayo, 2004](#)). Pregnancies which occur during the post-partum estrus in a lactating female are often extended by delayed implantation 7–16 days beyond the normal 19 or 21 days of gestation ([Bronson et al., 1996](#)).

Manipulation of Breeding Cycle

Mice, more than rats, are strongly affected by pheromones which are chemical substances secreted from the body to elicit a specific behavioral reaction in the recipient.

Mice show three well-documented pheromone-driven responses which are used to help synchronize estrus and breeding.

Lee-Boot Effect

A group of females together housed together will tend to go into anestrus (or pseudopregnancy) and stop cycling for a period of time. Even smelling a male mouse will counter-act this effect, so the animals must be truly removed from male mice.

Whitten Effect

Introducing a male mouse to a group of non-cycling females will cause 40%–50% of those females to show estrus within 3 days and a second estrus in about 11 days. This can be used to synchronize ovulation in mice that would be

super-ovulated as ova/embryo donators, used as embryo recipient mice or to control breeding intervals to synchronize pup arrival.

Bruce Effect

Pheromones from an unfamiliar (different strain) male mouse may cause delayed implantation, pseudopregnancy or abortion in female mice bred within 24 h to 4 days of introduction (depending on strain). This effect is not seen if the new male is the same inbred strain as the female (Silver, 2008). Females pregnant over five days will not be affected by a new male introduced to the cage, so when pairing new couples, it is prudent to introduce the new male after the fifth day of gestation. The male is more likely to accept the pups as his own if they are born while he is in the cage (as opposed to being introduced to a new female after her litter is born).

Some of strains of rats may show mild Whitten effects but the literature is divided about this. It is generally agreed that rats are not susceptible to the Bruce effect. Rats, in general, do not seem to be as sensitive to pheromone effects as mice.

Post-Partum Estrus

Post parturition estrus occurs usually within the first 12–24 h after birthing. Approximately 50% of the time the post-partum estrus is fertile. This can make it possible for a new litter to be born to a mother who has not fully weaned her previous one. Optimal pup survival depends on close attention to weaning on-time when the post-partum estrus is used. It is important to have a system to track breeding and expected weaning dates!

Determination of Pregnancy

Rats' gestation period is 21–23 days with conception rates of 85% or better for outbred animals, slightly lower for inbred animals. At about 10 days, experienced palpation of the rat's abdomen can detect fetuses (easier to feel after 12 days). Mammary glands and nipple development become evident at 12–14 days.

Mouse gestation is about 19–21 days. An increased rate of weight gain may be noted during daily weight measurements at about 13 days into gestation. Fetuses may be very gently palpable mid to late gestation. Mammary structures develop beginning about 9 days and are pronounced by day 14. The abdomen is noticeably enlarged by day 14 as well.

Breeding Systems

Monogamous

Monogamous systems (1 male to 1 female) are used in both the rat and mouse species depending on the strain and aggression tendencies of the parents. Monogamous systems require more male animals and more labor to be sure litters are removed prior to the next parturition. Monogamous systems maximize the numbers of litters per female but litters may be smaller with slower growth rates over the lifetime of the female.

Colony Mating

In a colony mating scheme, one male and 2–6 females may be housed together. The young are removed at weaning. This system is efficient for space and labor, as the post-partum estrus is utilized, however tracking individual female production and specific maternal parentage of offspring can be challenging. Pups will be allowed to nurse off several females, especially if pups are close to the same age. Accurate record keeping of breeding and birth dates enables prompt removal of weanlings prior to the arrival of the next litter.

Polygamous or Harem Mating

In this scheme, one male is housed with 2–6 females but the females are moved to separate cages before parturition. The post-partum estrus is lost as a breeding opportunity; however females tend to produce larger young with more animals weaned per litter. There are a lowered number of total litters per the life of the female rat and there is an increased labor cost with more individual cages.

Some females can become territorial, so it is best practice to place the female animal in the male's cage. Once bred, females will not accept another male until the pregnancy terminates.

Generating and Maintenance of Genetic Lines

Generating and maintaining specific desirable genetic lines of animals is done both by general pet breeders as well as scientists. In the past, spontaneous mutations were recognized and bred – resulting in many inbred strains of interest. Now scientists can genetically engineer animals, where, simply stated, a specific gene can be inserted into or removed from an animal's gene pool and the effects studied. A very short list of genetic alterations includes animals which are prone to obesity or diabetes, rats that become spontaneously hypertensive, animals that lack specific parts of their immune systems, and animals that develop signs consistent with Parkinson's disease or Alzheimer's disease, animals with genetic modifications that include a genetic "switch" to turn the modification on and off.

Sophisticated techniques of superovulation, genetic manipulation and embryo transfer are used in labs to generate new strains of mice and rats (transgenic and chimeric animals). Once the genetic modification is established, careful breeding for about 20 generations stabilizes the mutation into a recognized strain of animal. Once that strain is stabilized, careful out breeding must occur to decrease inbreeding and maintain hybrid diversity. Breeding to establish and maintain stable genetic lines is a skill!

Superovulation

Superovulation is used to generate embryos for collection and transfer to living recipients or freezing (cryopreservation) for storage of desirable strains. Female animals are chemically induced to ovulate a greater number of eggs than normal at a predictable time. After treatment with hormones, the animals are mated (by a fertile or infertile male depending on desired outcome) to stimulate egg release into the oviduct. Eggs may be surgically collected from the oviduct for in-vitro fertilization (if not already fertilized), development into blastocytes and freezing or implant (see below). For reviews of technique see [Silver \(2008\)](#) or [Luo et al. \(2011\)](#).

Embryo transfer

Embryo transfer serves at least three purposes: to support a genetic line which has difficulty reproducing, to develop disease free animals or to manipulate genetics. Embryo transfer is performed by transplanting embryos from a donor animal into a pseudopregnant recipient. It is necessary to generate a number of recipients at the same time by bringing multiple females into estrus at the same time.

Most strains of mice can be brought into synchrony relatively easily using the Lee-Boot and Whitten pheromone effects discussed above. Rats are not as susceptible to pheromone manipulation and require chemical synchrony ([Rouleau et al., 1993](#); [Borjeson et al., 2014](#)). Not all females will cycle as predicted but usually over 50% can be brought into a state close enough to estrus to be tested with a vasectomized male. For technique review, see [Silver \(2008\)](#).

Parturition

Rats and mice have a hemotrichorial placenta with multiple layers separating the fetal and maternal blood flow (humans have hemodichorial) ([Benirschke, 2011](#)). Average litter sizes are 6–12 pups. Nursing is usually allowed only after all the pups are delivered. Rodent mothers become better mothers with age behaviorally but "fetal wastage" (a measure of loss of fetuses as animals age) increases with age due to implantation failure and post-implantation mortality. Stress and strenuous maternal exercise can lead to increased fetal wastage as well ([Mottola et al., 1993](#)). Dystocia is rare but may occur. Cannibalism is not frequent and is a sign of maternal stress.

Mice

Mice should be supplied sufficient bedding material to build nests. Nest building behavior is an important external indication of the animal's general health. First litters tend to be the smallest with production in mice improving after the 2nd litter. There are strain differences in gestation length and size of litters produced between strains (for example the average litter size of BALB/CJ mice is about 5, where the average litter size of FVB/N mice is about 9 ([Silver, 2008](#))).

Mother mice will retrieve scattered pups and return them to the nest. She will lay over the top of the pups to nurse. In cages with more than one litter, the young may suckle several lactating dams.

Rats

Many rat strains will build shallow nests beginning about 5 days prior to birth of the litter. About 1.5–4 h prior to the first pup there may be a clear mucoid fluid noted from the vagina. The female will move about the cage, stretching and then lie on the floor with the rear legs extended off the cage floor. As the pups come, she will consume the placenta. The entire process takes approximately 1.5–3.5 h depending on litter size.

Dystocia

Since most births occur during the dark period of the photoperiod, an animal found laboring in the morning should be suspected to be in dystocia. Causes of dystocia may include uterine inertia, malposition of the pups or obstruction of the birth canal. Consult a veterinarian. To treat dystocia, the state of the mother should be assessed. If she is exhausted, dehydrated, quiet or lethargic, the wisdom of trying to treat the dystocia vs surgical delivery of the pups should be considered. The birth canal should be examined and if a pup is found, it should be gently delivered if possible.

If chemical treatment of dystocia is elected, the following actions could be considered. Support the mother with subcutaneous fluids (such as LRS with 2.5% dextrose – about 1 cc per 10 g body weight), extra warmth and perhaps antibiotic if considered necessary. Oxytocin (0.3–4 IU/Kg) may be given intramuscularly or subcutaneously. For mice, one can dilute 20 IU Oxytocin in 1 cc of LRS and give approximately 0.1 cc subcutaneously or IM. Give the animal approximately 30–60 min. If there are no more pups produced, surgical extraction is recommended.

Post-Partum

Pups are altricial (born in an undeveloped state) and require feeding and care from their mothers. The pups are blind, hairless and their ear canals are closed. The larger the litter, the smaller the pups will be. Retina's take about a month to mature; even though the animals' eyes open prior to that, they are not fully visual. Maternal antibody is transferred across the yolk sac in utero and from colostrum in the milk. It is recommended that newly born pups be left undisturbed for the first 2 days if possible to allow full bonding with the mother; however some early quiet careful observation of pups may be prudent, especially when developing a new genetic strain (Wells, 2016). When changing cages for the first time after parturition, moving the nest and some dirty bedding into the new cage helps smooth the transition.

Rats

The external ear opens at about 2.5–3.5 days and pups appear to be able to hear at about 9 days. Incisors erupt about 6–8 days of age. Pups are generally fully haired by about 7–10 days of age. Eyes open at about 14–17 days of age.

Mice

Pups are called “pinkies”. When they are weaned, they are called “hoppers”. These terms are used by breeders (and reptile feeders) to identify the size of mouse. Mouse pups are mildly transparent and the white “milk spot” can be observed in their stomachs after they have nursed. They are fully haired by about 10 days of age and their eyes open at about 12 days of age. They can begin eating solid food and drink water at about 14 days of age.

Weaning

Weaning is generally done at about 21–28 days of age. Rats can be weaned as early as 17 days but 20–21 days (40–50 g body weight) is standard. Inbred strains may need to be more time before weaning. One indication of readiness for weaning is when pups remain very active when the cage cover is removed. If they just sit still, they are still too young and should not be weaned (Burd Connor, 2007). Recently weaned pups should be kept together by gender at least one week to help maintain body temperature.

If mothers are not bred on the post-partum estrus, most females will resume cycling about 2–4 days after weaning. If the post-partum estrus was used, wean the litter before a new litter is produced. Competition between the older animals and the newborns can cause injury to the newborns and the mother may not have enough milk for all the offspring.

Orphans

Wikipedia features a nice article about how to raise an orphan mouse (see Relevant Websites section). See that article for more specific details.

The best way to raise an orphan less than 10 days old is to try to foster it onto a mother of similar aged pups (within 1–2 days). Rub orphans with scented material from the “natural” nest (perhaps moist dirty bedding, feces and birth fluids if the litter is that young), then mix the new pup(s) in with the original pups in the nest. Without disturbing the cage, recheck in several hours. If the mother has gathered the babies together, she will most likely accept them.

If the pup is over 10 days old, the pup may be able to be hand raised but this is difficult to do successfully. Kitten Milk Replacer can support baby rodents. Baby rats and mice cannot urinate or defecate on their own, so their genitals should be gently stimulated with a soft moist q-tip or cotton after feeding. Do not allow them to get chilled!

Trouble Shooting Breeding Problems

If there are problems with breeding of strains, it is important to look at the husbandry and environment of the animals as well as the specific animals themselves. Temperatures in the wrong range, presence of vibrations or disturbing ultrasound noise, multiple disturbance of the cages (explosive noise, people opening and closing the cages), absence of nesting materials, dietary fat content (too much or too little) all can have an effect. It may take some investigation to determine the cause of breeding issues. For a checklist of questions to consider, see [Perret-Gentil \(2015\)](#).

Honey Bees, Royal Jelly, Epigenetics

Benjamin P Oldroyd, Rebecca J Reid, Alyson Ashe, and Emily J Remnant, University of Sydney, Sydney, NSW, Australia

Caste

Bee, ant and wasp societies are characterized by their 'castes'. Colonies typically contain a single reproductive queen and hundreds or thousands of workers that rarely if ever lay eggs. Queens and workers are morphologically distinct; in many species greatly so (Fig. 1, Snodgrass, 1956). In honey bees, for example, queens lack the pollen baskets, honey stomach and the elongated tongue of workers, so they are incapable of foraging. Workers, on the other hand, have all the specialized equipment for foraging, but lack a spermatheca (sperm storage organ) so they cannot mate and have far fewer ovarioles (typically 10 across both ovaries) than do queens (typically 500–600). There are physiological differences too; queens typically live one or 2 years and up to 5 years, whereas workers live about a month.

Queens and workers arise from genetically similar eggs, and so the different morphologies of queens and workers are entirely environmental in origin. In honey bees the developmental differentiation between workers and queens is mediated by one factor only: larval diet. That such fundamental differences in morphology, physiology and behavior can be caused by environmental cues is unusual in the animal kingdom.

How Queens and Workers are Made

When a queen honey bee lays a fertilized egg the egg is 'totipotent', that is it can be reared either as a queen or a worker. (This fact is the basis of the queen bee production industry – by creating the right environment for larval development, a beekeeper can produce almost limitless numbers of queens.) Fertilized eggs are laid by queens in either of two kinds of brood cells – the large, peanut shell-shaped queen cells that hang down off the normal brood comb, or the much smaller horizontal cells that comprise the worker brood comb (Fig. 2). (Queens also lay eggs in intermediate-sized drone cells, but these develop as male drones, and we shall not consider them further here). Whatever kind of cell an egg is laid in, eggs hatch after 3 days producing a tiny larva, about the size and shape of a plump letter 'c' in an 8-point typeface. In both queen cells and worker cells the newly-hatched larvae are fed by nurse workers – young bees. The food is a mixture of secretions from the salivary glands, and in the case of workers, regurgitated stomach contents (Shuel and Dixon, 1960). Both queen larvae and worker larvae are fed similar amounts of food for the first 2 days of life and are always provided with more food than they can eat (Nelson *et al.*, 1924). After 2 days, however, the diets change. Queen-destined larvae are fed a hyper-abundance of royal jelly. Queen larvae 'float' (actually hang) in a glob of about one milliliter of royal jelly, and it is remarkable that both jelly and larva do not fall out of the cell. Nurse workers continuously top up the royal jelly in queen cells, so there is always far more than the larva can eat. In contrast, worker larvae that are more than 2 days of age are 'progressively' provisioned. Worker larvae are only 30 min or so from starvation.

By the time a larva is 3.5 days old it loses its totipotency. If 3 day old larvae are transferred from worker cells to queen cells containing royal jelly, they do not develop as queens but will either die or develop as a worker or inter-caste (Weaver, 1957). Similarly, if a larva is transferred from a queen cell to a worker cell at 1 day of age it will develop as a worker, whereas larvae transferred after more than 1 day in a queen cell fail to develop in worker cells (Weaver, 1957).

Fig. 1 A queen bee (centre and marked with a disk numbered 74) is surrounded by her workers. The workers are much smaller than the queen. Photo B. Oldroyd.

Fig. 2 Peanut shaped queen-cells hang down from a comb constructed of worker cells in a dwarf honey bee *Apis florea* colony. Photo M. Rickets.

Royal Jelly is Responsible for the Differential Development

It is unequivocal that royal jelly is the key environmental determinant of whether a larva develops as a queen or a worker, and not the cell size or cell orientation. Queens can be reared in the lab in the horizontal orientation, provided that the diet contains substantial amounts of fresh natural royal jelly (Kamakura, 2011). It is mostly the greater size of the queen cell, and not its orientation, that causes nurse workers to feed queen larvae and worker larvae differentially (Shi *et al.*, 2011), though there is some evidence that worker larvae ‘beg’ for food (Beekman *et al.*, 2000). Thus the orientation and size of the brood cell is only important in determining what and how much the larva is fed by nurse workers, and is unimportant to how the larva develops.

Royal jelly is a thick, cream-coloured jelly. It contains proteins, amino acids, carbohydrates, fatty acids, vitamins and minerals (Townsend and Lucas, 1940). ‘Worker’ jelly fed to young worker-destined larvae differs from ‘royal jelly’ fed to queen-destined larvae in that royal jelly contains more carbohydrate (about 33% on a dry weight basis) than worker jelly (12%). However the proportion of sugar in worker jelly increases to 47% as worker larvae age (Shuel and Dixon, 1959). It seems likely that the carbohydrates (mostly glucose and fructose) that are present in the jelly fed to older workers are derived from honey regurgitated by nurse workers.

About 90% of the proteins in royal jelly belong to a class of proteins known as the Major Royal Jelly Proteins (MRJPs) (Schmitzova *et al.*, 1998). There are nine MRJPs that are coded by a group of clustered genes on chromosome 11. The *MRJP* genes are related to the *yellow* gene family, a common class of genes in insects, and the cluster of *MRJP* genes is flanked by five *yellow* genes (Drapeau *et al.*, 2006). This kind of arrangement suggests that the *MRJP* genes were derived from *yellow-e3* by gene duplication. Interestingly, it seems likely that *yellows* are bacterial in origin, and were horizontally transferred to insects early in insect evolution (Drapeau *et al.*, 2006). *Yellow* proteins are highly conserved and have multiple roles in insects including pigmentation, sex determination and behavior (Drapeau *et al.*, 2006).

All nine MRJPs are found in royal jelly (Schmitzova *et al.*, 1998), and presumably have a nutritive role. But they are also expressed in diverse tissues including ovaries, testes, head and brain suggesting additional functions (Drapeau *et al.*, 2006).

Three Hypotheses for the Trigger for Queen Development Contained in Royal Jelly

The mechanism by which RJ causes queen development is controversial and far from being resolved. Resolution is hampered by wildly different estimates of the constituents. It is unclear whether this is due to analytical inconsistencies or because the constituents are indeed highly variable.

Below we list three plausible hypotheses for the caste-determining property(ies) of royal jelly, noting that (1) and (2) are mutually exclusive, but (1) and (3) are not. In other words, there may be caste-determining factors in royal jelly, but they must be consumed in large amounts to make a queen.

- (1) There is some specific factor(s) in royal jelly, absent from worker jelly, which converts the developmental path toward the queen phenotype.
- (2) There is some specific factor(s) in worker jelly, absent from royal jelly, which converts the developmental path toward the worker phenotype.
- (3) After 2–3 days of age, queen-destined larvae are fed a super-abundance of food, and continue to feed on mass-provisioned royal jelly during the last larval instar after the brood cell is sealed. Worker-destined larvae are progressively provisioned and do not feed after the brood cell is sealed (Beetsma, 1979).

Royalactin, a Candidate Queen-Determining Protein From Royal Jelly

In 2011 Masaki Kamakura published a paper in *Nature* suggesting that the most abundant protein in royal jelly, *Major Royal Jelly Protein 1* (MRJP-1) is necessary and sufficient to cause the development of the queen phenotype (Kamakura, 2011). MRJP-1, which Kamakura called ‘royalactin’ is heat-unstable, and completely degrades after storage at 40°C for a month (Kamakura, 2011). Royal jelly stored in this way cannot induce the queen phenotype in lab-raised larvae, whereas fresh royal jelly can. Addition of purified royalactin to stored royal jelly rescues its queen-producing properties (Kamakura, 2011). This is good evidence that royalactin is the key queen-determining factor, though of course one might argue that its an open question as to whether royalactin is causative agent of queen development, or contributes indirectly to the development of queenliness (e.g., by acting as an appetite booster), without causing it. Kamakura proposed that royalactin directly interacts with the mTOR gene network, which regulates cell proliferation and is known to regulate development in insects. In particular, Kamakura showed that royalactin alters the expression of the gene *epidermal growth factor receptor* (*Egfr*), which is part of the mTOR pathway.

Unfortunately, the role of royalactin in queen development is far from resolved. Kamakura’s study was criticized, and more prosaic functions for royalactin were proposed by Buttstedt *et al.* (2016), who were unable to replicate Kamakura’s study and suggested that the real function of royalactin is to act as the thickener that stops royal jelly from running out of vertical queen cells. Its also difficult to see how a protein that forms a heteromer of four individual royalactin proteins bridged by the sugar apismin (Mandacaro *et al.*, 2017) could cross the gut wall intact and directly alter gene expression.

Nutritional Castration

As we have seen, worker-destined larvae are fed less than queen-destined larvae, and there is less sugar in the jelly fed to worker-destined larvae. Asencot and Lensky (1985) argued that it is the additional carbohydrates, particularly fructose, that are present in royal jelly in greater abundance relative to worker jelly, that cause larvae to consume more food, going so far as to suggest that the physical engorgement of the intestinal tract triggers increased juvenile hormone production and the development of queenliness. More recently it has been shown that genes in the insulin-signaling pathway, which respond to carbohydrates in the diet, also influence caste development (Wang *et al.*, 2013). Asencot and Lensky (1988) were able to rescue the queen phenotype by adding carbohydrate, particularly fructose, to worker jelly, which increased consumption. This is not to discount the likely role of the amount of food a larva has available to consume, as well as the amount of sugar that is in it, in caste development. In summary, there is good evidence that meager amounts of brood food that are low in fructose increase the likelihood that a larva will develop as a worker.

p-Coumaric Acid in Pollen and Nectar May Inhibit Queen Development

Mao *et al.* (2015) have argued that it’s not so much what’s in royal jelly, but what it lacks, that may be the key caste-determining factor. Almost all pollens contain phenolics that affect gene expression in insects. Thus, inclusion of pollen in the diet of older larvae may enhance worker development over queen development because it lacks plant phenolics. However, to us, this seems an unlikely basis for caste differentiation. Even though all pollens may contain at least some phenolics, the amount and kind is extremely variable, so this seems an unreliable way to determine caste. Further, there are many social insects (termites, ants and wasps) that do not consume pollen, yet still have caste differentiation.

Epigenetics and Caste Determination

The development of an organism is dependent in part on gene regulation. To overly simplify a complex process, in order for a cell in your big toe to do its job properly it needs to express different genes in different networks, and the tissue that contains it needs to develop in a different way from the cells in your liver. Major contributors to the regulation of gene expression in eukaryotes include histone acetylation and methylation, mechanisms that change RNA translation post-transcription, and DNA methylation (Box 1).

The information contained in a DNA molecule resides in the sequence of four bases, cytosine, guanine, thymine and adenosine that make up much of the molecule. However the genomic information contained in the sequence of bases is flexibly modified as part of the context-specific gene regulation process. DNA is packed tightly around proteins known as histones. Histones are subject to chemical modifications that affect the level of expression of associated genes. Further, the DNA itself can be modified by the addition of a methyl group to cytosines. Cytosine methylation generally reduces transcription, and a gene that is highly methylated will have reduced expression. Cytosine methylation is mediated by DNA methyltransferases (Dnmt 1 and 3), whereas removal of methyl groups from cytosines is mediated by TET dioxygenases (TET 1–3) that convert 5-methylcytosine to 5-hydroxymethylcytosine (Box 1).

One of the most important discoveries of the honey bee genome project (Weinstock *et al.*, 2006) was that the honey bee has a full set of DNA methyltransferase enzymes (Wang *et al.*, 2006). This was a surprising finding because the only other insects that

Box 1: Epigenetic mechanisms

Epigenetics refers to a range of modifications that alter gene expression and phenotype, without altering the DNA nucleotide sequence. In this way, epigenetic mechanisms change how the genome is regulated to facilitate cellular differentiation, developmental processes and to respond to changes in the environment. Epigenetic modifications are implicated in diverse regulatory activities across the genome, ranging from gene regulation and alternate splicing, to the suppression of transposable elements, chromosome inactivation and genomic imprinting (Paulsen and Ferguson-Smith, 2001; Jaenisch and Bird, 2003; Glastad *et al.*, 2011; Drewell *et al.*, 2012).

Epigenetic mechanisms can involve modifications to chromatin structure via histones (such as histone acetylation and methylation), modifications to cytosine residues via DNA methylation, or post transcriptional regulation of genes by noncoding RNA molecules such as small RNAs.

DNA methylation is one of the most important and well understood mechanisms of epigenetic modification. The process of DNA methylation involves the covalent bonding of a methyl group to a DNA cytosine residue. In animal genomes, methylation usually occurs at CpG dinucleotides. DNA methyltransferase (DNMT) enzymes catalyse the methylation of cytosine nucleotides. DNMT1s are maintenance enzymes that copy existing methylation patterns onto newly synthesized DNA strands during DNA replication. DNMT3s target unmethylated cytosine residues to establish new methylation patterns (Schaefer and Lyko, 2007).

Methylation in mammals and plants occurs widely throughout the genome, including in promoter regions, transposable elements, and the introns and exons of genes (gene bodies) (Yan *et al.*, 2015). Mammals have high levels of DNA methylation; 60%–90% of CpG dinucleotides are methylated (Lister *et al.*, 2009). In mammals promoter region methylation acts to repress gene transcription (Bird, 2002).

Insect methylation profiles are quite different from those of mammals and angiosperms. In insects, DNA methylation is restricted to gene bodies, and occurs at a much lower frequency than in mammals; just 0.2%–8% of CpG dinucleotides genome-wide are methylated (Feng *et al.*, 2010; Zemach *et al.*, 2010). Methylation within gene bodies is thought to regulate alternative splicing (Suzuki and Bird, 2008).

had been sequenced at the time, fruitfly and mosquito, did not have a functional DNA methylation system. Soon it was discovered that indeed, many honey bee cytosines are methylated, and that the methylation patterns seemed to differ between castes, suggesting that methylation helps mediate cast differentiation (Lyko *et al.*, 2010). This observation provided a clue to the mechanism by which larval diet might affect gene expression and change the course of development in worker and queen-destined larvae; epigenetic modification of the genome via DNA methylation.

DNA Methylation and Caste Determination

The corpora allata sits beneath the brain of insects, where it produces Juvenile Hormone (JH). JH has profound effects on insect growth and development. In honey bees, JH is involved in caste differentiation (Asencot and Lensky, 1984; Mutti *et al.*, 2011). The corpora allata is nearly twice the size in queen-destined larvae than it is in worker-destined larvae as a result of polyploidization (duplication of chromosomes) (Kucharski *et al.*, 2008). DNA methyltransferase 3 (DNMT-3) is the key enzyme that mediates de-novo methylation of DNA cytosines. DNMT-3 is highly expressed in the corpora allata of honey bee larvae, hinting that methylation of genes in the corpora allata may be central to the process of cast differentiation. Honey bees respond well to RNA interference technology, and this allowed Kucharski *et al.* (2008) to knockout expression of DNMT-3 in young larvae. Larvae so treated developed as queens, suggesting that indeed methylation of key genes prevents development of the (default) queen phenotype, steering the developing larva toward a worker.

While the specific genes that orchestrate caste polymorphism as a result of differential methylation are unknown, there is at least one strong candidate. *Dynactin p62* is expressed in the corpora allata, where it is involved in the regulation of juvenile hormone levels. This gene has higher levels of methylation in worker-destined larvae than in queen-destined larvae. Experimental knockdown of DNMT-3 expression results in the queen pattern of methylation of *dynactin p62* (Kucharski *et al.*, 2008), and the queen phenotype. No doubt there are other genes and processes involved, but this is an extremely exciting finding.

Other Epigenetic Factors Potentially Involved in Caste Determination

One of the components of royal jelly, phenyl butyrate, acts as a histone deacetylase inhibitor (Lyko *et al.*, 2010) (see Box 1 for a description of histones and chromatin in gene regulation). Histone deacetylases may act to suppress transcription by removing acetyl groups from histones and compacting chromatin (Kouzarides, 2007). They are known to interact with DNMTs (Jaenisch and Bird, 2003).

Small RNAs, including microRNAs (miRNAs), piwi-interacting RNAs (piRNAs), and short interfering RNAs (siRNAs) are small noncoding regulatory molecules that are necessary for many cellular processes, including epigenetic regulation (Mattick and Makunin, 2006; Carthew and Sontheimer, 2009). They can control chromatin structure and mediate intergenerational epigenetic inheritance (Ashe *et al.*, 2012).

Fig. 3 Model showing some of the main factors affecting differential caste development in the honey bee. Reproduced from Maleszka, R., 2008. Epigenetic integration of environmental and genomic signals in honey bees. *Epigenetics* 3, 1–5 with permission.

A variety of small RNAs are found in the jelly provisioned to developing honey bee larvae. Worker jelly is enriched with miRNAs compared to royal jelly, with miRNAs of greater abundance and complexity suggesting that miRNA secretions by nurse bees may contribute to the regulation of caste development (Guo *et al.*, 2013). Queen and worker bees differ in miRNA expression profiles (Ashby *et al.*, 2016) and queens also express higher levels of piRNAs compared to workers (Wang *et al.*, 2017). piRNA expression may be related to germline suppression of transposable elements in reproductive queens compared to sterile workers, but may also have developmental roles in caste-specific phenotypes.

Putting it All Together

Thus far in this article we have learned that larval nutrition is the key factor in determining caste development and that epigenetic modification of gene networks arises as a consequence of differential nutrition of queen-destined and worker-destined larvae. But what connects the two? We summarize the likely associations in Fig. 3. We emphasize that this is a working model, and much of the detail remains to be elucidated.

Nutritional signals, including the amount of dietary carbohydrate and royal jelly protein available to and consumed by larvae, interact with the insulin signaling and mTOR gene networks within the fat body of the developing larva. In queen-destined larva these nutrition-sensitive gene networks cause changes in the polyploidization of the cells of the corpora allata, while simultaneously changing and generally decreasing methylation patterns genome wide. Increased JH production in the expanded corpora allata, and methylation changes, alter gene expression resulting in the queen phenotype (Fig. 3).

Conclusions

Although cast differentiation in social insects is one of the most extreme examples of phenotypic plasticity known in animals, and has been subject to considerable research over many decades, the actual mechanisms by which royal jelly changes the course of development is not understood. The role of royal jelly is beyond dispute, but the special ingredient(s) that cause the path to royalty remain to be elucidated.

The Genetics and Epigenetics of Life History and Reproduction: Fish

Matthew C Hale, Texas Christian University, Fort Worth, TX, United States

© 2018 Elsevier Inc. All rights reserved.

Many aspects of fish biology such as their rapid generation time, their high fecundity, and, for many species, their relative ease of housing in a controlled environment lend themselves to genetic and epigenetic studies. Additional feature, such as the wide array of mating systems used makes fishes an interesting taxonomic group coupled with variation in how sex is determined. Unlike in birds and mammals, sex determination in fishes is notoriously labile (Devlin and Nagahama, 2002; chapter 31 this issue), and closely related species can vary in the placement of the master sex-determining gene, the identity of the master sex-determining gene, or even if genetic sex determination is used at all. This diversity in sex determining mechanisms and mating systems coupled with a large array of adaptive phenotypes and life histories makes the fishes an ideal group to study adaptive biology and evolution. In this article I will discuss the genetic and epigenetic basis for the development of a few of the amazing adaptive phenotypes exhibited by fishes. These phenotypes will be discussed through the lenses of adaptation to maximize the fitness of the individual and how different forces of selection promote the development of different life histories in males and females. Specifically, I will focus on several reproductive behaviors; the evolution of anadromy and migration in the salmonids (salmon, trout, and char), the evolution of warm-water adaptation in Winter Skate, and the ability of the environment to alter sex in several species of fishes (Environmental Sex Reversal: ESR).

The recent development of next-generation sequencing methods has ushered in the “omics” era. These advancements have had an impact on genetic research in non-model organisms, allowing the collection of genome-wide and transcriptome-wide data, to answer evolutionary and ecologically important questions. Recently, these same methods have been adapted to studying the epigenome (modifications to the structure of DNA that are heritable but do not include mutations to the DNA sequence). Although the epigenome is more complex than the genome, and relatively few epigenetic marks have been investigated in detail, these new developments are extremely exciting for evolutionary biologists as more and more experiments suggest that the epigenome is important in the development of adaptive phenotypes. This will inevitably lead to many more discoveries that link changes in the epigenome to the development of adaptive traits.

The Genetic and Epigenetic Control of Life History Development: Anadromy in Salmonids

The salmonids (salmon, trout, and char) are a charismatic and economically important group of fishes native to high latitudes in the northern hemisphere. Their importance in native communities, sport fishing, and aquaculture has caused them to be well characterized at the genome level, resulting in sequenced genomes for both Rainbow Trout (*Oncorhynchus mykiss*; Berthelot *et al.*, 2014) and Atlantic Salmon (*Salmo salar*; Lien *et al.*, 2016). These complete genomes serve as an essential resource for further genetic research, as newly generated sequences can be aligned to these genomes to determine, amongst other things, the location of differentially expressed genes and the location of genomic variation (Single Nucleotide Polymorphisms or SNPs) associated with the development of adaptive traits. In sum, the large amount of genetic data available for salmon and trout makes them an excellent system for asking questions about the genetic basis of ecologically and evolutionarily important traits.

The salmonids are perhaps best known for their spectacular long-distance migrations that in some cases can take an individual from Canada to Japan. Migration is a fascinating behavior found in many taxonomic groups including birds, insects, fish, and mammals. The main reason individuals migrate is to take advantage of temporary resources that are either not present or are only present seasonally in their natal areas (e.g., food resources in the open ocean, or the summer emergence of winged insects in the Boreal forest; Dingle, 2006). Multiple studies on Rainbow Trout have found that many migratory related traits have considerable additive genetic variance, suggesting that migratory traits are heritable and are passed on from parents to their offspring (e.g., Hecht *et al.* (2015)). Despite this, very few studies have determined the genes associated with migratory related traits in any species (excellently reviewed in Liedvogel *et al.* (2011)). There are two reasons for this: (1) most migratory species do not have sequenced genomes and (2) it can be difficult to distinguish migratory individuals from resident individuals. This last point is especially important, as in many species where populations exhibit partial migration (i.e., where some individuals remain resident and others migrate) it is very difficult to visually distinguish migrants from residents. Salmon and trout represent an excellent system for studying the genetic basis of migration as not only are there two completed genome sequences available, but migrants and residents develop clearly differentiated phenotypes that allow for easy identification of an individual's migratory status (see Fig. 1).

All salmon and trout hatch and spend a portion of their early lives in freshwater. At some point in development (variable depending on species and population) migratory individuals must prepare for leaving their natal streams (see Fig. 2 for the life cycle of anadromous salmon, char, and trout). Salmonids display variation in life history tactics depending on the population and/or the species. Some species (such as Pink (*O. gorbuscha*) and Chum Salmon (*O. keta*)) are obligate migrants in their native areas, whereas most other species are partial migrants in at least part of their range. Migration can take different forms. Some populations, such as Brook Trout (*Salvelinus fontinalis*) in the North American Great Lakes regions, are potadromous (migrating from streams to large bodies of fresh water) whereas other populations are anadromous and migrate from freshwater streams to the ocean. Regardless of the type of migration, all migratory individuals undergo a physiological process called smoltification that prepares migrants for leaving their natal streams. The end-result of smoltification is to change juvenile salmonids from dark-colored, freshwater

Fig. 1 Phenotypic differences between resident and smolt *Oncorhynchus mykiss* juveniles after smoltification. Both photographs were taken on the same date and both fish are of the same age. The photograph clearly shows the difference in coloration between residents and smolts and the change in body shape. Both features are typical of smoltification and are required before a smolt can migrate to the ocean. Figure taken from Baerwald, M.R., Meek, M.H., Stephens, M.R., *et al.* 2016. Migration-related phenotypic divergence is associated with epigenetic modifications in rainbow trout. *Molecular Ecology* 25, 1785–1800, see references for a complete citation. Permission was obtained from Wiley.

Fig. 2 Life history development in salmonids that show partial migration, such as Rainbow Trout, Sockeye Salmon, Chinook Salmon, Brook Trout, Dolly Varden, and (rarely) Atlantic Salmon. All salmonids hatch in freshwater. They then spend a portion of their lives in freshwater (from a couple of weeks in Pink Salmon, to several years in Chinook and Sockeye Salmon). At the point in development marked by ★ individuals either stay in freshwater (In species or populations that show partial migration) or undergo the smoltification process and move to a pelagic environment for a variable portion of time before returning to their natal streams to spawn. Figure kindly provided by Krista Nichols.

Fig. 3 Changes in plasma hormone levels during smoltification in Atlantic Salmon. Data for plasma hormonal levels are normalized to the January time point. Note, similar patterns of hormonal change have been noted in other salmonids in the lead up to smoltification, especially in Chinook Salmon and Rainbow Trout. Hormones are: Prolactin in red, IGF-1 (insulin growth factor-1) in yellow, Growth hormone in orange, Thyroxine (T₄) in blue, and cortisol in green. Modified from McCormick, S.D., 2013. Smolt Physiology and Endocrinology in Fish Physiology, pp. 199–251.

adapted parr into streamlined, pelagic adapted silvery smolts (see Fig. 1). The process of smoltification is characterized by increases in lipid metabolism, protein synthesis, changes in behavior, and, in anadromous individuals, hypo-osmoregulatory ability (Hoar, 1976; Dickhoff *et al.*, 1997). These changes require upregulation of several hormones including, growth hormone (GH), thyroid hormones (especially T₄), and cortisol (See Fig. 3: McCormick, 2009). These changes are especially demanding of anadromous individuals, as the physiological demands of moving from freshwater to seawater are stronger than moving from rivers to lakes. As a result, most research on smoltification has been dedicated to anadromous populations of Atlantic Salmon and Rainbow Trout. After spending a variable portion of time utilizing the extensive resources in the pelagic environment, migratory individuals begin returning to their natal streams. On their way back home, migratory individuals undergo sexual maturation in preparation for spawning, and in so doing, begin the next generation.

Timing of the smoltification process is critical, as the length of time that smolts have to complete smoltification and migrate to the ocean is limited (the so called “smolt window”). Key to the timing of this process is the coordinated upregulation of several hormones shown in Fig. 3. Indeed, experimental modifications of these hormones results in a reduction in the number of individuals that undergo smoltification, and, for individuals that do smolt, reduced survival in seawater. Several of these hormones (such as growth hormone and prolactin) are peptide hormones that are synthesized via the processes of transcription and translation. Others, such as thyroid hormones and cortisol are either synthesized directly by the endocrine system, or are modified from steroids. Regardless of the chemistry of the hormone receptors are required for hormones to initiate their desired effect and these receptors are transcribed and translated from the genome. Therefore, there is a link between the genome and the action of hormones, and this link allows for adaptation at the genome level.

Due in part to these large-scale physiological changes migration is a costly process. Not only do these changes incur a significant energetic cost, but migratory individuals also suffer from increased predation and disease compared to residents. Therefore, migration must present sufficient benefit to overcome these costs. The underlying driving force behind migration is access to nutrient rich foods that are absent, or in limited supply, in many natal freshwater streams. The result of increased access to nutrients is abundantly clear when migratory salmonids return to spawn. Migratory individuals are larger and more fecund than residents and are better able to compete for access to breeding sites (redds). However, this size discrepancy between residents and migrants serves to vary the benefit of migrating between the sexes.

Sexual Maturation and the Decision to Migrate

In salmon and trout, undertaking a migratory life style requires individuals to delay their sexual maturation until they return from the pelagic environment. As all salmon and trout breed in freshwater, sexual maturation precludes migration (although note that there are examples of male salmonids (jacks) undergoing maturation in freshwater and then migrate to the ocean). The nutrient availability in the pelagic environment leads to sex bias in the propensity to migrate, with multiple studies reporting a strong female-bias in both the proportion of out-migrating smolts and in the proportion of returning spawning adults. Body size has a stronger influence on fecundity for female salmonids than it does for males. Larger females are able to devote more energy to producing eggs than are smaller (resident) females, whereas it is the number of matings a male can obtain that determines his reproductive success (Quinn *et al.*, 2011; Fleming, 1998). Therefore, in partially migrating populations, females receive more benefit to migrating than males. Further supporting this hypothesis, Ohms *et al.* (2014) found a consistent female-bias in out-migrating

Rainbow Trout from nine river catchments along the Pacific coast of the United States and Canada, with an average female proportion of out-migrating smolts of 63%. Similar results have been found in other partial migrant salmonids including Brook Trout (*Salvelinus fontinalis*; Theriault *et al.*, 2007), and Dolly Varden (*S. malma*; Koizumi *et al.*, 2006), suggesting this is a feature common to partially migratory salmonid populations. Interestingly, multiple studies in Rainbow Trout have not reported a significant male-bias in resident populations both above and below barriers (Sloat and Osterback (2013), Ohms *et al.* (2014); but see Rundio *et al.* (2012)). It is possible that many of the populations reported in Ohms *et al.* (2014) favored residency over anadromy, as populations with lots of anadromous individuals typically report a high proportion of male residency. It is important to note that different populations display partial migration differently, as the occurrence of such a process is influenced by population genetics (discussed below), environmental variance, and differences in demography.

Tied into the differences in the sex ratio of migrants and residents are the energetic demands of the process of sexual maturation. In most species, the timing of sexual maturation is not uniform (Taranger *et al.*, 2010). Sexual maturation is governed by the release of hormones from the brain that stimulate cellular development in the gonads. In salmonids sexual maturation occurs once individuals have reached a certain body size and have the energy resources necessary for reproduction, and, although multiple studies have documented the energetic requirements for sexual maturation, the exact size, lipid concentration, and physiological status that are required for the initiation of sexual maturation are, for the most part, unknown (Thorpe *et al.*, 1998).

The Genetic Basis of Migration

The cost-benefit tradeoff to migrating is a key reason why many salmonid populations exhibit partial migration. In these populations, whether an individual undergoes migration or remains resident depends on the interplay between the environment and genetics (Dodson *et al.*, 2013). Studies in Rainbow Trout have shown that the propensity to migrate is highly heritable (Thrower *et al.*, 2004; Hecht *et al.*, 2015). Although resident fish can produce migrants and migratory fish can produce residents, there is evidence to suggest that migrants produced by residents have lower seawater survival than migrants with migrant parents. Research attempting to find the genes associated with the development of the migratory phenotype suggests that (1) migration is a complex trait that involves polymorphisms across the genome (e.g., Hale *et al.* (2013); See Fig. 4), and (2) there appears to be population specific genetic effects. However, migration in salmonids is also influenced by environmental factors such as food availability in natal streams, density of conspecifics, elevation, water flow, and the latitude at which a given population is located (Narum *et al.*, 2011). Most high latitude streams have limited resources, causing an increased proportion of offspring to undergo smoltification and migrate; as seen in Atlantic Salmon (Valiente *et al.*, 2005) and Arctic Char (Jorgensen *et al.*, 2013). Clearly, the development of the migratory phenotype in salmonids is a classic example of a complex quantitative trait, with influences both from genetics and the environment.

Fig. 4 GWAS plot showing association between migratory phenotype (resident or returning migrant) and 9990 polymorphisms scattered throughout the genome. Samples consist of 100 residents from Sashin Lake Alaska sampled in 2010 (56.365°N and -134.679°W) and 105 returning sexually mature adults sampled between 2006 and 2010 from Sashin Creek Alaska (56.379°N and -134.653°W). The Y-axis shows the $-\log_{10}$ of the P value (so higher values=smaller P-value). Chromosomes are alternatively colored to aid in comparisons. Modified from Hale, M.C., Thrower, F.P., Berntson, E.A., Miller, M.R., Nichols, K. M. 2013. Evaluating adaptive divergence between migratory and nonmigratory ecotypes of a Salmonid fish, *Oncorhynchus mykiss*. *G3-Genes Genomes Genetics* 3,1273–1285. Note that this figure was built by aligning sequences in Hale *et al.* (2013) to new version of the rainbow trout genome (as of June 2017).

This interplay between genotype and the environment can lead to extreme changes in the development of the different life histories from one year to the next. In some years environmental conditions may select the development of residents over migrants (e.g., Nichols *et al.*, 2008; Hale *et al.*, 2013). Such years would be characterized by abundant freshwater resources and limited competition from other fishes. On the other hand, the environment in these northern streams is often fickle, and in the following year the situation may reverse and there are limited resources in the same streams, and therefore many more migrants produced. While migration is known to be heritable, it appears that the underlying genetic basis for the development of migratory related traits is complex, and caused by either many genes of small effect or by other genetic changes. This last point is important for understanding the inheritance of migration, and potentially in using that information for conservation as many populations of anadromous salmonids in the lower 48 United States are declining. More fully understanding the genetic basis of migration could be a great boon to fisheries management in these regions as scientists could preferentially select individuals that are more likely to successfully migrate than individuals that have alleles associated with residency.

The Epigenetic Control of Migration in Rainbow Trout

Phenotypic plasticity describes the process that allows individuals to alter their phenotype in response to environmental change alter their phenotype due to new environments. Altering the regulation of gene expression is one mechanism that allows organisms to change the amount of mRNA produced in direct response to environmental variance. This change in gene expression allows for phenotypic plasticity, as changes in mRNA expression have a direct link to protein abundance. This ability to respond to environmental stimuli necessitates a molecular mechanism that permits RNA polymerase to change the amount of mRNA produced in the targets gene or genes. There are many different molecular mechanisms that can induce changes in gene expression, including histone modification, changes in DNA methylation, and changes in the production of noncoding RNAs. All of these changes can be grouped together as epigenetic modification, i.e., modifications that are passed on through successive generations but do not involve changes in the DNA sequence. Until recently, relatively little information was available regarding the effects of modifications on the epigenome and their potential influence on the development of different life history tactics. Baerwald *et al.* (2016) have investigated patterns of DNA methylation in both resident and migrant Rainbow Trout finding 57 regions of the genome with altered methylation patterns (so called differential methylated regions: DMRs) between the two phenotypes. The presence of these regions suggests that epigenetic changes in rainbow trout are associated with the development of different migratory phenotypes (Fig. 5).

However, it is important to note that not all individuals showed methylation patterns that were consistent with their migratory status. Three samples deviated from expected; two residents had methylation patterns characteristic of smolts, and one smolt possessed methylation patterns characteristics of residents. This suggests that there is epigenetic plasticity in the development of the migratory phenotype, which is not surprising given how variable patterns of gene expression are between migrants and residents (McKinney *et al.*, 2015; Hale *et al.*, 2016). More than 50% of the differentially methylated regions identified by Baerwald *et al.* were found within or next to CpG islands. CpG islands are regions of the genome rich in cytosine and guanine bases, are often found in or adjacent to promoter regions in the 5 prime untranslated region (UTR). These regions are extremely important in RNA polymerase binding and transcription initiation. Hypermethylation of cytosines in CpG islands is often associated with a decrease in the expression of downstream genes, as adding methyl groups to cytosine restricts access of the promoter region to RNA polymerase thereby decreasing transcription. Alternatively, hypomethylation of cytosine in CpG islands is more commonly associated with increased expression of down stream genes, as fewer cytosines are methylated. Baerwald *et al.* (2016) found evidence for hypermethylation of several genes in resident fish, including two genes connected to circadian rhythm signaling: aryl hydrocarbon receptor 2 alpha (*AHR2A*) and *RAS1*. Circadian rhythm pathways help organisms anticipate and prepare for changes in photoperiod, both with respect to daily changes in the light-dark cycle and to annual changes in photoperiod. Previous research has suggested that several circadian rhythm genes are connected to the smoltification process, including *CLOCK*, *BMAL*, and several Cryptochromes (McKinney *et al.*, 2015). Several of these genes are more expressed in the brains of migrants than they are in residents; Baerwald *et al.* found evidence for increased methylation in the promoter regions of *AHR2A* and *RAS1* in residents compared to migrants, providing a mechanism for increased circadian rhythm gene expression in migrants. The expression of circadian rhythm genes is important in the timing of outmigration, as many studies in salmonids have found that the window of time for leaving natal areas is narrow. As Baerwald *et al.* (2016) studied out migrating individuals, it is possible that these methylation changes provide a mechanism that allow migrants to be more sensitive to the time of year than residents.

Warm Water Adaptation in the Winter Skate

A commonly held viewpoint in evolutionary biology is an extension of Fisher's original evolutionary genetic theory: i.e., that in order for populations to be able to adapt to changes in the environment, the population in question must have considerable genetic variation. A natural consequence of this is that populations or species with reduced genetic variation will be less able to adapt to environmental change. This is especially concerning for species of conservation concern, as such species will typically have reduced genetic heterozygosity (due to population bottlenecks and low effective population sizes) and therefore, in theory, will be less able to adapt to changing environments. However, this does not mean that such populations or species are doomed to extirpation or extinction. Recent research has shown that changes in gene expression (i.e., being phenotypically plastic) can allow for rapid adaptation to novel environments. For example, studies in the Winter Skate (*Leucoraja ocellata*) have shown a link between changes in

Fig. 5 Heatmap showing clustering of differentially methylated regions (DMRs) between smolts and residents. Each column represents an individual two-year old rainbow trout: Green columns represent residents, blue columns represent smolts. Each row represents a DMR that was statistically significant between phenotypes, the darker the red, the more methylated that individual is for that DMR. DMRs below a minimum read depth of 10 were excluded and are represented as grey boxes. Figure taken from Baerwald, M.R., Meek, M.H., Stephens, M.R., *et al.* 2015. Migration-related phenotypic divergence is associated with epigenetic modifications in rainbow trout. *Mol. Ecol.* 25, 1785–1800; see reference list for full citation). Permission granted for use was obtained from Wiley.

gene expression and exposure to increased water temperatures (10°C warmer than most of the species range), proving that some Winter Skate have been able to adapt to novel environments. Lighten *et al.* (2016) used RNA-seq technology in a comparative framework to determine patterns of gene expression between warm and cold water Winter Skates. They found substantial changes in gene expression between these two forms of Skate, confirming that changes in gene expression allow rapid adaptation to new environments. Although varying patterns of gene expression are well known to be linked to adaptation to novel (and in some cases, very different) environments in several species of fish (for example in stickleback and killifish), in very few cases have those changes in gene expression been linked to an underlying mechanism. While technological limitations have long made studying epigenetic changes difficult, recent advances in Next Generation Sequencing techniques are allowing researchers an increased understanding of the epigenome, and its involvement in adaptation and evolution.

Epigenetic Control of Sex Reversal in Fishes

As mentioned in the beginning of this article, one aspect of fish biology that sets them apart from other vertebrates is the multitude of sex determination systems that they employ. Broadly speaking, evolutionary biologists split these mechanisms into two groups: genetic sex determination (GSD) and environmental sex determination (ESD). However, a key feature of sex determination in fishes is the ability for some species to undergo environmental sex reversal (ESR). ESR describes the ability of the environment to override the individual's karyotype resulting in the development of the opposite sex. In other words, ESR produces XY females in systems

with male heterogamety and ZW males in systems with female heterogamety. The Half-smooth Tongue Sole (*Cynoglossus semilaevis*) is a species with female heterogamety, however, environmental effects such as temperature cause about 14% of genetic females (i.e., ZW) to be functional males. Evidence from other species of fish, such as the Sea Bass (*Dicentrarchus labrax*), also reports similar findings, with temperature fluctuations causing ESR.

While many species of fish are known to exhibit ESR, the mechanisms responsible for these sex reversals are poorly known. Research on Sea Bass strongly suggests that epigenetic modifications are at least partially connected to the process of ESR. More specifically, Navarro-Martin *et al.* (2011) found methylation differences in the promoter regions of *cyp19a1a*, a gene strongly connected to female development in fishes, leading to decreased in *cyp19a1a* expression and male development. Thus, epigenetic change, induced by environmental variance, could modify the expression of important genes in the molecular pathways connected to sexual development and result in the development of the opposite sex than encoded by the karyotype. Research on the Half-smooth Tongue Sole found similar results, with high water temperature (>22°C) decreasing methylation of *dmrt1* (doublesex and Mab3 related transcription factor; a well-known candidate gene in vertebrate sex determination), increasing its expression and causing the development of functional males with the ZW karyotype (pseudomales: Shao *et al.*, 2014). The importance of *dmrt1* (and its homologs) in male development has already been discussed. However, research from both Half-smooth Tongue Sole, and Medaka suggest that environmental conditions can override its methylation, modifying its expression, and resulting in ESR (Shao *et al.*, 2014; Matsuda *et al.*, 2002).

That environmental variance can cause epigenetic change has far-reaching implications for the survivability of a population and ultimately, a species. The long-term effects of ESR could be problematic for the persistence of a population if ESR biases the sex-ratio in maladaptive ways (Ospina-Alvarez and Piferrer, 2008). The effects of global climate change for species with either ESD or ESR will require animals to either adapt quickly to these new environmental conditions, or move to new areas that have not (yet) felt the consequences of climate change. This potentially puts such populations under considerable pressure. Evolutionary, ESR can also result in problems as it necessitates that pseudomales (or pseudofemales in a XY system) develop methods to combat the expression of genes that promote the development of the phenotype encoded by the karyotype, (i.e., female development in ZW systems or male development in XY systems). Such genes would presumably be of detriment for the homogametic sex, and therefore their expression would need to be controlled. ESR clearly shows how changes in epigenetics caused by variation in the environment can have a large effect on the phenotype of the affected individual. Like the previous examples in the Half-smooth Tongue Sole and Rainbow Trout, it is clear that epigenetic modifications can cause the development of different phenotypes. These phenotypes may not always be adaptive, and in such circumstances the longevity of a population or species might be in jeopardy.

Conclusions

Both genetic and epigenetic modifications are clearly important in the development of many life history characteristics in fishes. It has been known for some time that development of adaptive phenotypes is caused by changes in the genome (e.g., freshwater adaptation in sticklebacks: Colosimo *et al.*, 2005; Hohenlohe *et al.*, 2010). More recently, microarray and RNA-seq studies have reported that changes in gene expression are also linked to the control of many adaptive phenotypes. However, such studies (usually) do not provide a mechanism that allows for gene expression to change. Epigenetic modification directly interacts with the structure of the DNA, altering the configuration of the DNA around target genes, and therefore changing the ability of the gene to be transcribed. Here we provide some examples of phenotypic plasticity enabled by modifications of the epigenome that allow adaptive phenotypes to develop. However, we are just beginning to understand how important epigenetic modifications are in the development of adaptive traits. Recent technological advancement will facilitate the collection of both genome and epigenome data that can be used to look for links with the development of adaptive phenotypes. Certainly, the fishes offer an excellent opportunity for asking these questions making this an exciting time to be studying evolutionary biology in fishes.

Genetics & Epigenetics in Life History and Reproduction: Oysters

Mackenzie Gavery and Steven Roberts, University of Washington, Seattle, WA, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Oysters represent a cosmopolitan molluscan taxa with a rich diversity of reproductive strategies that makes them a unique study system from a comparative physiology perspective. Oyster sex is greatly influenced by the environment and most species demonstrate varying degrees of hermaphroditism. In addition to having fascinating reproductive biology, oysters are ecologically and economically important marine invertebrates. They serve a critical ecological niche, serving as habitat and, as benthic filter feeders, contributing to the removal of excess organics, nutrients, and particulates. Additionally, several oysters species have gained culinary prominence, supporting fisheries and aquaculture industries. Commercial and recreational harvest of wild populations contributes to local economies and provides an important source of protein and nutrients. Aquaculture of bivalve species such as oysters has ancient origins, but has increased in recent decades. Today, shellfish aquaculture accounts for 76% of marine aquaculture production worldwide (FAO, 2012). The oyster that makes up the majority of the production and harvest worldwide is *Crassostrea gigas*, regionally referred to as the Pacific oyster (Fig. 1(a) and (d)). In addition to *Crassostrea*, there are several other families in the order *Ostreidae*, considered 'true oysters', including *Ostrea* and *Saccostrea*. *Pteroida* is another oyster order that represents the pearl oysters such as those in the genus *Pinctada*.

This article will cover what is known regarding sex determination and gametogenesis in oysters from a genetics and epigenetics perspective, with a focus on *Ostreidae*. Most of what is known comes from studies in *C. gigas*, as this species has received significant scientific attention given its high commodity value. This includes a genome sequence (Zhang *et al.*, 2012) that has contributed to understanding the molecular underpinnings of reproductive biology. Much of what is known about reproduction in oysters relates

Fig. 1 Images of oyster life-stages and farming practices (a) adult *C. gigas*, (b) histological slide of a hermaphroditic *O. lurida* developing both male and female gametes, (c) *O. lurida* veliger larvae (planktonic stage), (d) *C. gigas* aquaculture in Washington, United States using long-lines, (e) *C. virginica* aquaculture in Mississippi, United States using off-bottom floating bags.

to aquaculture and the desire to control gonad development. Before getting into molecular aspects, we will first provide a survey of life history strategies, paying particular attention to reproduction. This article concludes with perspectives on the role of epigenetic processes in oyster reproduction and future directions of research that could provide a mechanistic connection between environmental conditions and reproduction.

Life History Strategies

As juveniles and adults, oysters are sessile, benthic organisms inhabiting intertidal and subtidal marine and estuarine environments. Oysters, like many marine invertebrates, exhibit an r-selected reproductive strategy, meaning they produce a high number of 'cheap' offspring, but relatively few survive to maturity. While juvenile and adult oysters are sessile (Fig. 1(a)), early developmental stages are planktonic (Fig. 1(c)). Interestingly, from a comparative physiology perspective, various oyster genera within the order *Ostreidae* take different approaches to larval investment.

Oysters of the genera *Crassostrea* and *Saccostrea* are gonochoristic, alternate hermaphrodites with low but consistent frequency of simultaneous hermaphroditism (Coe, 1936). Some species, such as *C. gigas*, are protandric, meaning they mature first as males then as females in subsequent seasons. However, recent studies have reported that *C. gigas* is capable of changing sex within a single spawning season (Yasuoka and Yusa, 2016). Oysters of these genera are broadcast spawners. Broadcast spawners release male and female gametes into the water column where external fertilization occurs. The larvae that develop from external fertilization are consequently free-living, and remain in the water column consuming primarily phytoplankton for a number of weeks, depending on the species and environmental conditions.

Alternatively, flat oysters of the genus *Ostrea* are viviparous and female oysters of this genus brood their larvae. Oysters in the genus *Ostrea* exhibit rhythmic consecutive hermaphroditism, where they can flip back and forth maturing as males then females and back again during a single spawning season (Coe, 1943). As may be expected with this strategy, histological observations of the gonad in *Ostrea* species tend to show both male and female stages (Fig. 1(b)) though they spawn only as a single sex at a time. Mature male *Ostrea* species will release sperm balls into the seawater enabling uptake into the mantle cavity of the female where fertilization occurs. Females will brood larvae in the mantle cavity for approximately 1–2 weeks depending on the species and environmental conditions, then release the shelled larvae into the water column where they will be planktonic for an additional 1–2 weeks. Compared to the broadcast spawners, brooding oysters produce relatively larger, but fewer number of eggs and sperm. Regardless of genus, larval oysters will end their planktonic stage once they are competent to settle on suitable substrate (such as the shells of conspecifics) and will metamorphose into juvenile oysters, sometimes referred to as 'spat', at which time they begin a sessile existence.

Sex Determination

Sex determination remains poorly understood in oysters as in other bivalves. The mechanisms underlying the high plasticity of sex in oysters, particularly in *Ostrea* species that alternate sexuality within a single season, remain a topic for future work. Nevertheless, there is evidence in *Crassostrea* species to support a combination of genetic sex determination (GSD) where sex is established at fertilization, and environmental sex determination (ESD) where sex is determined after fertilization in response to environmental cues. The following sections will describe what is known about genetic and environmental influences on sex determination in oysters, primarily in *C. gigas*.

Genetic Sex Determination

Heteromorphic sex chromosomes have not been identified in any oyster species examined to date. A vast majority of the evidence for a genetic basis for sex determination in oysters come from sex ratio studies, where the sex ratios of offspring from known parents is measured. The first evidence for GSD in oysters came from a study with controlled crosses in *C. virginica*, where significant differences in sex ratios were observed between families sired by the same male (Haley, 1977). Subsequently, Guo *et al.* (1998) extended these findings by evaluating sex ratios in pair-mated *C. gigas* families and also reported significant family and parental effects on sex ratio. Based on these results, Guo *et al.* (1998) proposed a single-locus model of sex determination in *C. gigas* with a dominant male allele (M) and a protandric female allele (F), such that FM oysters are true males and FF individuals are protandric females that have the potential to sex-change. This model was not sufficient to explain the heterogeneity in sex among families generated by a single male and different female parents, thus Hedrick and Hedgecock (2010) proposed a 3-genotype model with fixed females (FF) fixed males (MM) and protandric females (FM), and included additional parameter 'f' in the model, which is the probability that FM individuals will mature as females.

The models of sex determination in *C. gigas* were derived with no knowledge of the sex determining genes involved with this process. Support for a single major sex determining locus comes from a genetic analysis (i.e., quantitative trait loci, or QTL analysis) that identified a single locus moderately associated with sex in *C. gigas* (Hubert and Hedgecock, 2004). However, additional studies would be needed to rule out the possibility that other loci were also involved. Studies investigating genes involved in sex-determination are limited in bivalves, but have been recently facilitated by technological advances in the genomics field. In

general, the approach has been to identify and characterize orthologs of canonical sex determining genes in oysters to determine if the gene expression profiles are consistent with a role in sex determination. Initial studies were successful in identifying the presence of canonical sex determining genes in oysters including *Dmrt1* an important upstream regulator of male sex determination in mammals and *FoxL2* a conserved gene in female sex determination (Dheilly *et al.*, 2012; Teaniniuraitemoana *et al.*, 2014). However the expression patterns of these genes were not consistent with sex determining functions in oysters, meaning they were either expressed in the gonad of both males and females or in somatic tissues. The most comprehensive study to date comes from Zhang *et al.* (2014), who used a comparative approach to identify *C. gigas* homologs of major genes in sex determining pathway from both mammals and model invertebrates (*Drosophila melanogaster* and *Caenorhabditis elegans*). Here, they expanded the search of homologs in *C. gigas* to larger families of genes than had been previously investigated. They identified *Sox30* in *C. gigas*, a homolog to the mammalian sex determining *Sry* gene, which had a pattern of expression consistent with a sex determining function. They also identified *Dsx* (a transcription factor similar to *Dmrt1* that plays a role in male sex determination and differentiation mammals) and *FoxL2* (a transcription factor that plays a key role in female sex differentiation). Based on their findings, the authors proposed a model where *Sox30* is the major sex determining gene that is directly or indirectly linked with *Dsx* and *FoxL2*. This is the first time an *Sry*-like gene has been associated with sex determination outside of the vertebrates. Based on their findings (Zhang *et al.*, 2014), concluded oyster sex determination pathways are more similar to mammalian systems than invertebrates such as *D. melanogaster* and *C. elegans*. Additional work would be needed to follow up on this premise and also to determine how environmental factors influence sex determination.

Environmental Sex Determination

While there is clearly a genetic component of sex determination, genetics alone does not control sex in oysters, as various exogenous factors have been reported to impact sex ratios of oyster populations. Temperature has a significant effect on sex ratios in oysters. Typically high temperatures are associated with femaleness (Fabieux *et al.*, 2005; Lango-Reynoso *et al.*, 2006), but for some species, such as *C. corteziensis*, males are predominant at high temperature (Chávez-Villalba *et al.*, 2008). Food availability also has the ability to skew sex ratios in many bivalve species including *C. gigas*, where it has been shown that high food availability promotes the development of females (Lango-Reynoso, 1999). Exogenous steroids, such as 17beta-estradiol, have also been reported to skew sex ratios toward females in *C. gigas* when administered early (but not late) in development (Mori and Nakamura, 1969). Many of these studies examine the influence of exogenous factors on adult oyster sex ratios, but very few have studied the effect of environmental exposure at initial gametogenesis. An exception is a controlled laboratory study in *C. gigas* spat (i.e., recently metamorphosed juveniles) where sex-ratios switched from female to male-biased between 18 and 28°C (Santerre *et al.*, 2013). Interestingly, although *C. gigas* are reported to be protandrous (maturing as males first) more than half of the oysters in this study first matured as females under normal rearing temperatures, suggesting other factors, such as food abundance, may also be important for sex determination.

Gametogenesis

Just as with sex determination, environmental conditions influence gametogenesis in oysters. Temperature is a primary factor associated with gametogenesis but food availability and photoperiod are also important. Because temperature has such a strong influence on gametogenesis, it is not surprising that there is a large amount of variation in the timing and extent of reproductive output across geographic areas, and specifically latitudes (Berthelin *et al.*, 2000; Enríquez-Díaz *et al.*, 2009). Although there is variation among oyster species and even among populations within the same species, it is common for initiation of gametogenesis to occur in winter followed by an active phase of gametogenesis in spring when water temperatures increase. Maturation and spawning typically occur in summer followed by a resorption and resting phase. However, in addition to environmental factors, various aspects of oyster reproduction including reproductive timing and output have been shown to be under genetic control (e.g., Lannan *et al.*, 1980). Although a genetic effect has been identified, the role of genes and hormones continue to be explored. The remainder of this section will provide an overview of gonad development, followed by insight into gene and steroid hormone control of gametogenesis in oysters.

The gonad of oysters is a transient tissue. In *C. gigas*, the germline is specified by maternal cytoplasmic determinants (preformation) through the 4d cell lineage and larvae possess putative primordial germ cells (Fabieux *et al.*, 2004). Primordial germ cells will eventually give rise to mature male or female gametes, and when it comes to oysters, frequently both within the same individual. At the initiation of gametogenesis, small clusters of stem cells are scattered in conjunctive tissue. Then germ cells divide by mitosis and gonial proliferation induces the expansion of tubules that invaginate the area surrounding the digestive system. These developing gonadal tubules grow at the expense of storage tissue and at the final stage of maturation, prior to spawning, gonads completely fill the gonadal tubules. Gametogenesis is considered a period of negative energy balance in oysters due to the high metabolic cost of gamete production and a concomitant loss of up to 60% body weight (Mathieu and Lubet, 1993). As early as 1936, it was suggested that a connection exists between metabolism and reproduction in oysters (Orton, 1936). It is likely that the variation observed in the timing and extent of gametogenesis in oysters is influenced by the inherent ability of the oyster to store and metabolize glycogen. Molecular approaches have given insight into the role of energy storage and mobilization in the reproductive cycle in oysters. For example, expression of genes related to glycogen metabolism show seasonal variation in association with the gametogenic cycle

(Bacca *et al.*, 2005). Samain *et al.* (2007) reported significant differences in expression of glucose metabolism genes in oyster strains that vary in the extent of reproductive investment.

A seminal study by Dheilly *et al.* (2012) that examined transcriptome variation throughout reproductive development in *C. gigas* found over 2000 genes differentially expressed over the course of maturation in males and females, shedding light on genes involved both in early sex differentiation as well as gametogenesis. Using a microarray platform to study the gonadal maturation process in males (spermatogenesis) and females (oogenesis), Dheilly *et al.* (2012) identified a suite of genes indicative of these respective processes. A number of candidate genes for sex differentiation were identified in early stage gonad samples including *dpy1*, a histone methyltransferase essential for hermaphroditism in *C. elegans* (Hsu *et al.*, 1995) in early male gonads and *FoxL2* a highly conserved female specific transcription factor in early female gonads. In mature male gonads, a number of genes involved in ubiquitination and proteasomal degradation of ubiquitinated proteins were uniquely expressed. In females, there was evidence of elevated cell cycle activity in maturing gonads and interestingly *Methyl-CpG binding domain protein 2* (*MBD2*) was found to be highly expressed in mature female gonads. *MBD2* is involved in binding methylated DNA and thus presumably involved in gene regulatory activity. Dheilly *et al.* (2012) suggested the high expression of *MBD2* in developing oocytes may indicate an epigenetic transfer of information.

In vertebrates, sex steroid hormones are a critical part of reproductive physiology and regulate a variety of reproductive activities including sex differentiation, maturation and estrous cycles. However, unlike vertebrates, the role of sex steroids in sex differentiation is controversial in bivalves. Although findings can be contradictory, a majority of the evidence suggests that sex steroids are important regulators of bivalve reproduction involved in gametogenesis, vitellogenesis and spawning. All of the major sex steroid groups including estrogens, androgens and progestins have been identified in bivalves. Sex steroids may also play a role in regulating the metabolism of glycogen, proteins and lipids in bivalves. For example, injections of estradiol have been shown to stimulate glycogenolysis by regulating activities of glucose-6-phosphate dehydrogenase in *C. gigas* (e.g., Mori *et al.*, 1972). Vitellogenesis, an essential part of oocyte maturation in oysters, can also be regulated by estradiol (Matsumoto *et al.*, 1997). These results indicate the steroids may accelerate the metabolic rate in the gonad providing more energy to the maturing gametes.

Triploidy in Oysters for Aquaculture

In bivalves, as in most animals, nutrients and energy are required for two major physiological processes, reproduction and growth. By reducing the development of the gonad, more resources can be used for somatic growth. This has been exploited in oyster aquaculture through the use of non-reproductive triploid oysters. Triploidy is the state of an organism or cell having three sets of chromosomes in each nucleus, and differs from the natural diploid (two sets of chromosomes) state found in most animal cells. Triploid individuals are commonly sterile because homologous chromosomes cannot pair during meiosis. The benefits of triploidy in oysters is that reproduction is often accompanied by the deterioration in taste and quality of the flesh as glycogen stores are used up, thus triploid oysters can be harvested year round as quality does not decline during summer months when oysters would normally be sexually mature. It has also been shown that triploid oysters grow faster than their diploid counterparts (Allen and Downing, 1986).

Triploidy was first induced in oyster aquaculture in the early 1980s using chemical manipulation of fertilized eggs (Stanley *et al.*, 1981). Specifically, the compound cytochalasin B was used to chemically inhibit extrusion of the second polar body in fertilized eggs, resulting in the retention of two sets of maternal chromosomes and one set of paternal chromosomes. Currently, triploid oysters are produced through crossing tetraploid and diploid oysters. In this process haploid eggs from diploid females are fertilized by diploid sperm from tetraploid males. The first tetraploid oysters were generated in *C. gigas* and were obtained by inhibiting the first meiotic division of eggs from triploid females. Although a majority of triploid oysters are sterile, some individuals are capable of producing gametes that, under tight control, can be used to produce tetraploids. Triploid induction does not guarantee sterility and there are numerous reports of slow growing gonads and abnormal gametogenesis or gonads that are actually fertile. Temperature is an important factor here as well, as triploid oysters show higher rates of maturation under higher temperatures (Normand *et al.*, 2008).

Epigenetics in Oysters

The plasticity of functional sexual morphology coupled with the clear relationship between environmental conditions and gametogenesis suggests an intriguing role of epigenetics in oyster sexual differentiation and reproductive development. Epigenetics refers to heritable processes that alter gene activity without changes to the underlying DNA sequence (Jablonka and Lamb, 2002). In this respect, heritable could be used in a mitotic sense, such as heritable between cell divisions, and in some cases also in a meiotic sense meaning being passed to the next generation through the germ cells. Common epigenetic marks include DNA methylation, histone modifications and non-coding RNAs. All of these marks have been shown to have important roles in mediating processes involved in reproductive biology, though primarily in mammalian systems. One interesting exception is the work of Navarro-Martín *et al.* (2011) where they demonstrated DNA methylation of the aromatase promoter is mechanistically involved in temperature dependent sex determination in European sea bass. Specifically, elevated temperature was associated with increased methylation of the aromatase promoter, which silenced the expression of this key enzyme responsible for conversion of testosterone

to estrogen, thus resulting in masculinization. It has also been shown in the half-smooth tongue sole (*Cynoglossus semilaevis*), a fish that exhibits both GSD and ESD, that exposure to high temperature early in development induces a 'pseudomale' phenotype (sex reversed genetic female) that can be inherited at a high frequency in F1 offspring (Chen *et al.*, 2014). This phenotype is associated with an inherited pattern of DNA methylation on the sex chromosome derived from the pseudomale parent, implying a role for DNA methylation in maintaining this phenotype across generations (Shao *et al.*, 2014). These examples highlight ways in which DNA methylation may be playing a role in facilitating environmental responses to sex determination in species that, similar to oysters, exhibit a combination of GSD and ESD. The presumption remains that epigenetic processes are integral in the link between the environment and biological traits in oysters (Fig. 2), however, caution must be taken when extrapolating possible mechanisms to oysters as DNA methylation landscapes are strikingly different between vertebrates and invertebrates and thus functional roles could differ.

DNA methylation in oysters, similar to other invertebrates, is much lower than vertebrates. Whereas approximately 70%–80% of CG dinucleotides are methylated in vertebrate genomes (Bird and Taggart, 1980), only about 15% are methylated in oysters, where it is further limited in the genome to primarily gene bodies (Gavery and Roberts, 2013). Even considering this dramatic difference in pattern between vertebrates and invertebrates characterization of DNA methylation patterns in *C. gigas* indicate that this epigenetic mark has an important role in regulating gene expression (Gavery and Roberts, 2013). There have not been any studies carried out to look specifically at the regulatory role of DNA methylation in oyster reproduction, but some studies have assessed DNA methylation pattern in gametes. A study by Olson and Roberts (2015) showed that DNA methylation patterns in sperm between related individuals were more similar than unrelated individuals. A recent study by Riviere *et al.* (2017), found dynamic temporal DNA methylation patterns across development from oocytes to spat.

While most of the studies examining epigenetics in oysters have targeted DNA methylation, there have been efforts to describe miRNA and histone modifications, though none have been specifically designed to determine their role in sex determination or differentiation. Certainly one of the most intriguing aspects of environmentally induced epigenetic changes is the potential for epigenetic information to be transferred meiotically from parent to offspring via gametes. One example of how this may be accomplished is through the transmission of histone modifications in mature gametes. It has been shown in both mammals and zebrafish that during spermatogenesis, when most histones are replaced with protamines, certain modified histones are non-randomly retained and tend to mark important early embryonic development genes, suggesting that these marks may have a role transferring epigenetic information to the embryo (Brykczynska *et al.*, 2010; Wu *et al.*, 2011). Histones are not replaced with protamines in bivalve sperm as they are in mammals (Eirín-López and Ausió, 2009). Rather, canonical histones are replaced with various sperm nuclear basic proteins that can be classified as either protamine-like type, histone-type or protamine-type (Ausio, 1986; Eirín-López and Ausió, 2009). It will require additional work to determine to what extent canonical histones and variants are retained in bivalve sperm, but this avenue of research could be very valuable toward a greater understanding of the potential transmission of epigenetic information from parent to offspring in bivalves. Histone modifications themselves remain largely understudied in shellfish, but it has been reported that bulk histone methylation levels and the expression of histone demethylases were responsive to temperature during development, suggesting a role for histone modifications in mediating the physiological responses of oysters to temperature (Fellous *et al.*, 2015). Because of the importance of temperature in sex

Fig. 2 An organism's genotype and the environment it encounters contribute to traits (phenotypes). Increasingly it's been shown that an organism's epigenetic information also contributes to phenotypes. Unlike the genome, the epigenome can be directly impacted by the environment, providing mechanisms to allow an organism to respond or adapt to external changes, and perhaps even transmit these induced traits to offspring.

determination and gametogenesis in oysters, additional studies on the role of histone modifications during these processes will be important.

Another important class of epigenetic marks that remain wholly uncharacterized in bivalve molluscs are regulatory microRNAs (miRNAs), though genes for miRNA biogenesis have been detected in available bivalves genomes (Rosani *et al.*, 2016). It has been shown that miRNAs exhibit sex-biased expression in the reproductive axis of vertebrates such as chicken (Bannister *et al.*, 2009) and Atlantic alibut (Bizuyeyu *et al.*, 2012). Furthermore, miRNAs have been shown to play an important role during gonadogenesis in insects (e.g., Jin and Xie, 2007). Given the increasing evidence for the essential role of miRNAs in reproduction, it is likely that characterization of miRNA expression patterns during gametogenesis in oysters will provide insight into regulatory mechanisms of this process.

An often underappreciated taxa, oysters offer a unique system to explore the intersection of genetics and the environment and their respective roles in reproductive biology. As described here, there are still significant gaps in knowledge with regard to mechanistic underpinnings of sex determination and gonad development. Given that oysters are found worldwide in susceptible ecosystems, coupled with an expanding suite of genomic resources, there will likely be a focus on the oyster to help define the role of epigenetic phenomena in mediating genotype by environment interactions.

Nutrition and Reproduction in Fish

Helene Volkoff and Sydney London, Memorial University of Newfoundland, St. John's, NL, Canada

© 2018 Elsevier Inc. All rights reserved.

Introduction

Nutrition is crucial to the reproductive performance of all vertebrates, including fish. Successful reproduction requires adequate resources in order to sustain the high-energy demands for the production of gametes and reproductive behaviors. In most cases, negative energy balance and low food consumption inhibit the reproductive axis.

Fish are the largest and most diverse vertebrate group, yet very little is known about the interactions between nutrition and reproduction in fish and only a small number of studies have evaluated the effects of feeding on early and adult reproductive performance. Although species-specific variations occur, decreased food availability or nutrient-deficient diets in fish generally cause gonad regression, a decrease in spawning, and a decrease in the number of eggs produced by a female. In contrast, increased food availability promotes growth and larger body sizes, and causes earlier maturation and production of a higher number of eggs.

Life Stages in Fish Reproduction and Energy Demands

The fish reproductive cycle consists of a series of stages with the final purpose to obtain a progeny through the fertilization of eggs by spermatozoa (Fig. 1). The success of reproduction thus depends on the successful progression through each stage of the reproductive cycle, nutrition being crucial for some of these stages.

When immature (sexually quiescent) fish reach a given size, they undergo puberty. As they mature, they will begin producing gametes and exhibiting sexual behavior. In both males and females, the reproductive cycle involves two major phases; the phase of gonadal growth and development (gametogenesis), and the phase of maturation, which involves gamete release and spawning. After spawning, gonadal recrudescence (resting phase) may occur in some species.

External fertilization is common in fish. Most fish are oviparous, meaning that females will release their eggs into the environment to be fertilized. However, there are some species that are viviparous, where internal fertilization takes place, and developing eggs/embryos are retained in the maternal reproductive tract to produce live young.

Once mature, many fish exhibit seasonal changes in their reproductive cycle, which are dependent on annual variations in environmental factors. Spawning/mating usually occurs at specific periods of the year that coincide with optimal environmental conditions for the growth of the offspring. Depending on the species, these conditions can include food availability, water temperature and photoperiod among others.

During the maturation phase of the adult reproductive cycle, gonads develop until they reach a maximum size during the spawning season and produce gametes. Both the production and the release of gametes are under hormonal control (see below). During egg formation, females invest considerable energy to provide the eggs with nutrient stores (i.e. the yolk/vitellogenin). Some species, known as capital breeders, store energy prior to breeding, drawing on it later during reproduction, therefore reducing the extent to which reproductive success is dependent on environmental conditions at the time of breeding. Other species, known as income breeders, will feed during spawning, using the energy of food directly for reproduction. Salmonids, for example, are extreme capital breeders as they stop feeding before their upstream migration to the breeding grounds.

Whereas females seem to invest considerable energy in gametogenesis, males might use more energy in reproductive behavior. In several species, the courtship of females by the male is a complex and energetically costly behavior, involving swimming, parading, and fighting. Although most oviparous fish leave their eggs after spawning, some species invest energy in parental care by preparing nests and guarding the eggs, or by not feeding while carrying the eggs in their mouth (e.g. cichlids, some catfish). Viviparous species display parental care by offering protection, and in rare cases provide maternal nutrients (some poeciliids, some sharks), which are an energy investment for the female.

A variety of methods are available to assess reproductive condition in fishes, including examination of the gonads, measurement of sex steroid levels, and gonadal indices. The gonadosomatic index (GSI) is the relative size of the gonads as a proportion of total body mass. It is widely used as an indicator of reproductive stage as it increases with the maturation of the fish, being maximal during the peak period of maturity and declining shortly after spawning. Fecundity (number of eggs produced by fish expressed either in terms of eggs/spawn or eggs/body weight) is also used as a measure of the reproductive capacity of female fish.

Endocrine Control of Reproduction/Dual Endocrine Control of Reproduction and Metabolism/Feeding

In fish, as in other vertebrates, reproduction is coordinated by the hypothalamus-pituitary-gonadal (HPG) axis. The hypothalamus produces gonadotropin-releasing hormone (GnRH), which regulates the synthesis and release of pituitary gonadotropins, including luteinizing hormone (LH) and follicle-stimulating hormone (FSH). The gonadotropins act on the gonads to stimulate

Fig. 1 Schematic representation of the life cycle of fish, and the major steps affected by nutrition (stars).

gonadal development through the secretion of sex steroid hormones. These steroids, in turn, feed back to the brain and the pituitary (Fig. 2). Feeding and reproduction are regulated by many endocrine factors produced by both the brain and peripheral organs (e.g. gastrointestinal tract).

The endocrine system plays an important role in regulating internal responses based on changes in the external environment. It also acts as a mediator between physiological systems, including feeding and reproduction. Animals often modulate their reproductive physiology according to available energy stocks. For example, food limitation, which depletes energy stocks, inhibits the HPG axis in order to save energy supplies for vital functions. In both mammals and fish, a number of peptides have been identified that regulate both feeding and reproduction. These include brain factors such as neuropeptide Y (NPY) and orexin, as well as peripheral factors such as leptin and ghrelin.

Effect of Nutrition on Fish Reproduction

Fish are often faced with reductions in food availability (and thus the ability to store energy) during their natural life cycle, in particular during seasonal cycles and spawning migrations. The sensory and endocrine systems of fish recognize when external and internal conditions, such as size, age, and storage of macromolecules (sugars, amino acids, and lipids), are optimal for reproduction. Reproductive development can be completed if conditions are optimal, but may be delayed/terminated under non-optimal conditions. In cases of "malnutrition", females often exhibit more serious reproductive problems (inhibition of vitellogenesis, oocyte maturation and spawning) than males (decreased sperm volume and diminished milt fluidity, which can affect negatively the success of egg fertilization). However, the mechanisms involved are not yet clear.

Fig. 2 Major interactions between the endocrine regulators of appetite and reproduction in fish, and influences of nutrients. Red lines indicate inhibition.

Effects of Food Restriction

There is a high variability in the reported effects of fasting on fish reproduction. This may be due to the large variation in both age and size at puberty in different fish species, and between males and females of the same species, with the growth in males typically slowing at a smaller size and age compared to females (e.g. sea bass, halibut). As in all vertebrates, puberty in fish occurs when individuals have reached optimal age and size, having accumulated sufficient energy reserves to meet the nutritional and energetic requirements of maturation. It has been suggested that the onset of puberty in fish is in part linked to absolute levels or rates of accumulation of lipid stores. Increased plasma sex steroid levels also usually accompany puberty.

The onset of puberty can initially have positive effects on appetite and somatic (body) growth, with larger individuals in a population undergoing puberty earlier than smaller individuals. However, as puberty progresses, energy is reallocated from

somatic growth to gametogenesis and reproduction-related behaviors, such as migration and/or sexual behavior. Appetite is often reduced just prior to and during large parts of the spawning season. Studies show that, in some species, restricted feeding reduces energy stores and adiposity, and can reduce the percentage of fish that complete maturation, thus delaying puberty.

In many species, reducing the feeding rates of mature fish during the reproductive cycle decreases growth, GSI, gonadal maturation, and spawning frequency (or spawning duration) during the reproductive season. There are also gender specific responses to food restriction, with females being more sensitive. Food-restricted females often experience decreases in final oocyte maturation and egg quality, and produce smaller eggs/hatched larvae compared to those fed full rations. In some species, fasting in females decreases brain GnRH and plasma estradiol levels. In immature female coho salmon, for example, prolonged fasting impairs endocrine function by reducing growth-related hormones (IGF-1), gonadotropins, and sex steroid levels. Therefore, it is evident that fasting inhibits the HPG axis, showing a clear relationship between food intake and reproduction.

Effect of Food Quality on Fish Reproduction

Lipids, proteins, and carbohydrates are nutrients metabolized by the body to produce the energy needed for various physiological processes and physical activities. In fish, there are considerable inter-species differences in the requirements of these nutrients and the ability to use them. These differences are associated with the natural feeding habits of fish, which can be classified as carnivorous (meat eaters), herbivorous (plant eaters), or omnivorous (those who eat both plants and meat). Carnivorous species use dietary protein and lipids very efficiently for energy but are not efficient in using dietary carbohydrates. Conversely, herbivores and omnivores can use carbohydrates and require less dietary protein than some carnivorous species. Vitamins (A, E, and C) and minerals are also important nutritional factors for fish (Table 1), and fish living in different environments have different dietary requirement (marine vs. freshwater fish). Regardless, nutrition is related to growth and can interfere directly or indirectly with several aspects of fish reproduction, including gonadal development, reproductive performance, spawning rate, fecundity, the quality and quantity of egg/sperm, as well as progeny quality.

Lipids

Lipids are hydrophobic compounds that include triglycerides (“fats”), phospholipids, and sterols. They are indispensable to growth and the maintenance of structural and cellular functions. Triglycerides are composed of fatty acids and are the primary means of energy storage in animals. Phospholipids, which also contain fatty acids, are the main constituents of cellular membranes, and sterols, such as cholesterol, are precursors for sex steroid hormones, which are responsible of the development of the gonads. In addition, fatty acids are precursors for prostaglandins, which stimulate gametogenesis and sexual behavior. Lipids are also essential for the intestinal absorption of liposoluble vitamins. Dietary lipids consist mainly of triglycerides and essential fatty acids (EFA), which cannot be synthesized by the body. In fish, lipids are mostly stored in the muscle and liver, and are the main source of energy for growth and reproduction. They are mobilized during gametogenesis and, in females, processed into a yolk precursor (vitellogenin) in the liver, and transferred to the ovaries to be incorporated as nutritive material in the egg/yolk, serving as the main source of food for the future embryo. Low levels of dietary lipids and fatty acids have been shown to negatively affect reproduction and offspring success in fish. Females fed a diet high in fatty acids usually have higher quality and number of viable eggs, leading to higher fertilization, hatching, and offspring survival rates. In males, high fat diets increase the production and release of sperm with higher motility and increase the levels of male sex steroid hormones. However, an excess of dietary lipids has also been reported to cause inadequate protein intake and suppress growth in some fish.

Table 1 Overall effects of nutrition-related treatments on reproductive parameters in fish

<i>Treatment</i>	<i>Puberty</i>	<i>Maturation of gonads/fertility</i>	<i>Gamete quality</i>	<i>Spawning</i>	<i>Offspring survival</i>
Fasting	↓	↓	↓	↓	↓
Lipid deficiency	↓	↓	↓	↓	↓
Protein deficiency	?	↓	↓	?	↓
Carbohydrate deficiency	✖	✖	✖	✖	✖
Vitamin E deficiency	↓	↓	↓	?	↓
Vitamin C deficiency	?	↓	↓	?	↓

Phosphorus deficiency	?	?	↓	?	↓
Calcium deficiency	?	?	↓	?	↓
Probiotics supplementation	?	↑	↑	?	↑

Note: ↓, negative effects; ↑, positive effects; ✖, no known effects; ?, effects uncertain or not examined.

Proteins

Although lipids are the primary source of energy in fish, dietary protein provides essential amino acids, which are critical for growth and development, as they are necessary for enzymatic function and the formation of muscle tissue and sexual products.

Well-balanced proteins diets usually increase the mean total weight and the number of eggs produced/released by females. Conversely, low protein diets have been shown to alter GnRH and gonadotropin release, leading to an increase in maturation time, and reductions in reproductive performance, oocyte maturation, ovulation, and in the number of eggs produced and their viability. These effects are particularly pronounced in carnivorous fish, such as seabream, seabass and catfish. However, in some species, high protein diets can induce low reproductive performance, fertilization and hatching rates. Herbivore species, like pacu and rohu, are particularly sensitive to high levels of proteins. In addition, in all fish, providing excessive levels of dietary protein can result in increases the excretion of nitrogenous wastes, leading to high levels of ammonia in the surrounding water, which can negatively affect food intake, growth, and therefore reproduction.

Carbohydrates

Carbohydrates (CHO) are composed of simple sugars (i.e. glucose, fructose, galactose) and are found mainly in plants (usually stored as starches or cellulose). Though starch can be enzymatically broken down, cellulose is indigestible to most animals, including fish. The ability of fish to utilize dietary carbohydrates for energy varies considerably, and most species have limited ability to metabolize them. Some carbohydrates are deposited in the form of glycogen in tissues such as liver and muscle, where they are accessible as a source of energy. Some dietary carbohydrates are converted to lipid and stored in the body for energy. Omnivorous and herbivorous fish can metabolize high quantities of carbohydrates whereas carnivorous species use it less efficiently. Overall, fish do not appear to have a specific dietary requirement for carbohydrates. Consequently, very low carbohydrate levels generally do not compromise reproductive performance, but reproduction can be affected as carbohydrate levels increase proportionally in the diet. Complications only arise when carbohydrate levels are high, but tolerability depends on the species' feeding habits with herbivores (e.g. pacu) tolerating the highest levels, followed by omnivores and carnivores (e.g. seabass).

Vitamins

Vitamins are necessary for the normal growth, metabolism, health, and reproduction of fish, though in small amounts. Important vitamins include water-soluble vitamins such as vitamins B and C, as well as fat-soluble vitamins such as vitamins A, D, and E. Vitamins are often not synthesized by fish, and deficiencies may result in reduced growth and impaired reproduction. There are considerable differences in vitamin requirements among fish species, which depend in particular on their diet and the morphology of their gastrointestinal tract. Within a species, demands can also vary with age, size, and the physiological state of the fish (e.g. physical health, growth rate, stress level). All these factors may interfere with the ability of the fish to absorb, transport, and metabolize dietary vitamins. The most commonly studied vitamins in fish are A, E, and C.

Studies show that vitamin E influences the quality of the gonads, fecundity, egg quality, embryonic development, percentage of fertilization, hatching, and survival of larvae in both herbivores/ omnivores and carnivores. Its deficiency results in immature gonads, low fecundity and fertility, and reductions in hatching rates and fry survival. Conversely, higher levels of dietary vitamin E increases the development of gonads, GSI, gonadal maturation, egg quality and viability, hatching rates, and percentage of normal larvae.

Vitamin C (ascorbic acid) affects ovarian development, steroidogenesis, vitellogenesis, and embryogenesis. Low dietary vitamin C levels induce decreases in the reproductive performance of females, by reducing egg numbers, inhibiting hatchability, and increasing the number of deformed larvae and their mortality. However, it appears that males are less sensitive as sperm motility is unaffected by low vitamin C levels. Embryos and juvenile fish, on the other hand, seem more affected by vitamin C deficiency than adults, likely because this vitamin is necessary for the synthesis of collagen during embryonic development and growth. In females, higher vitamin C concentrations in the diet improve egg quality and development, with the contents of the maternal diet reflected in the contents of the egg.

During oxidation reactions, which occur during normal essential metabolic processes in the body, toxic free radicals can be produced. These molecules are highly reactive and can cause significant cellular damage (through a process called oxidative stress). Vitamin C and E act as antioxidant agents by inhibiting oxidation and therefore reducing the number of free radicals. Dietary antioxidant requirements increase during reproduction, as free radicals are produced in steroid hormone biosynthesis. Accumulations of free radicals can deteriorate membranes and the membrane integrity of both sperm and eggs. The antioxidant function of vitamins C and E provide an important protection for the gamete cells. The synergistic effect of the supplementation of vitamins C and E in fish feed is seen through higher egg and semen quality.

Inclusion of vitamin A (or its precursors, the carotenoids) in fish diets increases gonadal development, fertility rate, fecundity, egg size, and egg quality in many species, although high levels may induce mortality at some embryonic stages. Vitamin A is important for embryo and larval development due to its important role in bone development, retina formation, and differentiation of immune cells. Most vitamin A is stored in the liver with increased concentrations being observed during gonad maturation, suggesting a higher requirement of vitamin A during gametogenesis.

There is little information available on the effects of vitamins B on fish reproduction. Thiamin (vitamin B₁) is important for embryo survival and larval development, pyridoxine (vitamin B₆) is important in the synthesis of steroid hormones, and folic acid (vitamin B₉) has a role in hatchability of eggs.

Minerals

Minerals are inorganic elements necessary for normal body functions. They can be divided into macro-minerals, which are present at larger levels in the body and required in larger amounts in the diet (e.g. sodium, chloride, potassium and phosphorous), and micro-minerals (trace minerals), which are required in small amounts as components of enzyme and hormone systems (e.g. copper, iron, chromium, iodine, zinc and selenium). Fish require the same minerals as terrestrial animals but they can absorb many minerals directly from the water through their gills and skin, allowing them to compensate to some extent for mineral deficiencies in their diet. Minerals required in the formation of embryos, such as phosphates and calcium, are obtained through the vitellogenin in yolk.

Phosphorus is the most critical macro-mineral in fish diets because there is little of it in water and its absorption is limited. Phosphorus is a major constituent of hard tissues such as bone and scales, and is also required for various biochemical processes. Impaired growth and feeding efficiency, as well as reduced tissue mineralization and impaired skeletal formation in juvenile fish are common symptoms of a phosphorous deficiency. Phosphorus-deficient females can experience reduced fecundity, and their progeny might display low egg hatchability and high larval deformity rates.

Calcium is important in cell signalling, including the activation of eggs. In order for the eggs to begin development, they must be activated by the sperm. Once “activated”, the membrane of the eggs will harden upon contact with water. It has been shown that both the water-hardening and activation processes are calcium-dependent.

Micro-mineral deficiencies in the diet apparently do not affect growth or reproductive processes in fish, but may have a negative effect if the deficiency continues for an extended period of time.

Probiotics

Probiotics are live microorganisms that, when ingested in adequate amounts, exert a health benefit on the host. In fish, a wide range of microalgae, yeasts, and bacteria have been shown to act as probiotics, mostly with benefits in digestion, growth, and immunity. However, in some fish species, positive effects of probiotics on reproduction have been demonstrated as well.

In zebrafish, probiotics induce earlier maturation in juveniles, and increase larval growth, bone calcification and development of the gonads. In a number of species, feeding mature females with probiotics increase gonadal growth (GSI), fecundity, production and viability of fry, as well as embryo survival and hatching rate of larvae. These effects might be mediated by changes in expression of genes such those encoding GnRH, leptin, and vitellogenin.

Summary and Conclusion

Fish are an incredibly diverse group, making it difficult to generalize the effects of nutrition on reproduction. However, a clear relationship between the two has been established and it appears that overall, both the quantity and the quality of food are crucial for a successful reproductive cycle in fish.

Nutrition and Reproduction, Birds

Tony D Williams, Simon Fraser University, Burnaby, BC, Canada

© 2018 Elsevier Inc. All rights reserved.

Introduction

Small birds must find and eat enough food each day to satisfy their nutritional requirements and to maintain energy balance, though larger birds might balance energy and nutrient requirements over several days. In theory, reproduction should impose very different demands in terms of energy and nutrient balance compared with the non-breeding period: parents must find not only more, and potentially different, food to meet their own elevated metabolic demands from courtship, mating, incubation and parental care but in many (altricial) species, they also have to obtain large amounts of additional food to feed their growing offspring. Food availability, and potentially diet quality, are therefore widely assumed to be critical determinants of variation in breeding phenology, i.e., when birds breed, reproductive investment (e.g., the number and size of eggs produced), and overall breeding success (the number and quality of chicks produced). In addition, nutrition might play a role in carry-over effects whereby food intake or diet quality on the wintering grounds, or during pre-breeding migration, can impact reproductive decisions after arrival on the breeding grounds. In fact, data supporting each of these 'intuitive' ideas are surprisingly equivocal.

Generalists, Specialists and Seasonal Variation in Diet

In relation to foraging and diet selection, a long-standing dichotomy has been between "generalists", that eat a diverse array of foods, and "specialists" that eat only a narrow range of available foods – though these represent a continuum (Sherry, 2016). It is also now recognised that Individuals within the same species can often have different dietary niche preferences even in the same environment, i.e., they can show individual diet specialization (IDS) due either to genetic differences (e.g., sexually-dimorphic morphological feeding adaptations) or because of variation in learned behaviors (Bolnick *et al.*, 2003). Most birds are generalists and omnivores, eating a variety of animal and plant matter, although some species are extreme diet specialists, for example, snail Kites (*Rostrhamus sociabilis*) feed almost exclusively on *Pomacea* snails, and flamingos (Phoenicopteridae) rely on filter feeding on brine shrimp and blue-green algae while breeding.

At temperate and higher latitudes, invertebrate prey abundance can be relatively low in winter, so birds rely more on plant diets during these non-breeding periods. However, diet varies seasonally in most species since reproduction imposes different demands in terms of energy and nutrient balance. Insect diets therefore predominate in spring and summer, during breeding, to provide chicks with energy- or protein-rich food to support growth and development (Fig. 1). Thus, although adult birds can utilise a wide variety of food types during the annual cycle, young birds (chicks) are almost invariably reared on protein-rich, animal diets, for example, in the granivorous house sparrow, *Passer domesticus*, adults consume 97% plant matter but nestlings consumed 31% plant matter and 68% animal matter (Welty, 1975). Only a few species do not show diet shifts, with increased use of insect prey, associated with reproduction. In the house finch (*Haemorrhous mexicanus*) 97% of the diet consists of seeds, buds, flowers, leaves, and fruits throughout the year, and American and European goldfinches feed their chicks almost exclusively on thistle seeds breeding relatively late, in mid-summer, when these seeds ripen. Similarly, zebra finches (*Taeniopygia guttata*) are granivorous year-round, although they feed their chicks sprouting seed, made available by seasonal onset of rainfall, which have specific amino acid composition suitable for egg-production (similar to an insect diet; Allen and Hume, 1997).

Fig. 1 Seasonal variation in the percentage of seeds and insects in the diet of Horned Larks (*Eremophila alpestris*) in relation to breeding. Redrawn from Rotenberry, J.T., 1980. Dietary relationships among shrubsteppe passerine birds: Competition or opportunism in a variable environment? Ecological Monographs 50, 93–110, with permission from John Wiley and Sons, Inc.

Few birds rear chicks exclusively with frugivory (i.e., a fruit diet), in part because few plants fruit in spring and early summer in temperate and higher latitudes when most birds breed. Year-round availability of fruit is more common in the tropics, but tropical frugivorous birds can also switch to insect diets to feed chicks, due to the low nutritional quality of many fruits (Poulin *et al.*, 1992). Some tropical species select specific fruit diet to meet the mineral and energetic demands of breeding, starting with calcium-rich fruits during egg-laying, use of lipid- and iron-rich fruits through breeding, and protein-rich fruits supplemented with invertebrates (up to 25%–30% of diet) for protein to feed young (Lamperti *et al.*, 2014). Again, a very few tropical species rely on plant diets year-round including when feeding their chicks, for example, oilbirds (*Steatornis caripensis*).

Some species show unique adaptations to avoid problems of variation in natural food availability, or even no food availability! Many species cache or store food to survive periods of low food availability, though typically food is stored in summer and used during the winter. However, grey jays (*Perisoreus canadensis*) rely on cached food during the reproductive period and use this stored food to nest much earlier than other birds (Sechley *et al.*, 2014), laying eggs between late February–March when little natural food is available (and often incubating eggs in temperatures below -20°F). Pigeons (Columbidae) and Emperor penguins (*Aptenodytes forsteri*) both feed their newly hatched chicks “crop milk” a secretion from the lining of the crop or oesophagus that is regurgitated to young birds. Male emperor penguins feed their newly-hatched chicks this protein-rich “curd” after fasting for 110 days, until their female returns to the nest with food.

Specific Nutritional Requirements for Reproduction

Adult birds must find and eat enough food each day, or over several days, to meet their own nutritional requirements for self-maintenance, and during reproduction parents in altricial species must also find enough food for their chicks, to support growth and development. All birds therefore require variable amounts of energy, which they can obtain from carbohydrates, lipids, or protein, as well as vitamins and minerals. Certain “essential” nutrients must also be obtained from the diet because birds cannot synthesise these in sufficient quantities to meet their requirements. Although nutrient requirements have been estimated from controlled, laboratory studies of captive birds nutritional requirements of free-living birds are poorly known, especially during breeding, with the majority of studies focusing on total energy requirements (reviewed in Williams, 2012).

Seasonal variation in diet (described above) is assumed to reflect the need to provide chicks with energy- or protein-rich food to support growth and development. However, specific amino acid requirements are unknown for the majority of wild birds. Certain essential amino acids such as phenylalanine and tyrosine, and the sulfur-rich amino acids (SAA) methionine and cysteine are thought to be important for synthesizing egg proteins during egg formation, and lysine and methionine are the first limiting amino acids for growth. However, Murphy (1994) suggested that most birds could probably meet these specific amino acid requirements without selective foraging as long as they consume enough total protein in their daily diet.

Birds require similar essential micronutrients to mammals, including vitamins (e.g., vitamins A, B, D, E and K) and minerals (calcium, sodium, magnesium). Tropical avian frugivores and nectarivores are thought to have particular difficulty in meeting their mineral needs since many fruits are quite deficient in individual minerals. Calcium is probably the most limiting micronutrient in egg-laying birds (Burley and Vadehra, 1989) required to produce the calcium-rich egg shell. In passerines, production of a single clutch of eggs requires more calcium than is in the bird's entire skeleton. Small birds do not store much calcium for reproduction (Pahl *et al.*, 1997) and rely on daily intake of calcium-rich food (particularly snails). Many species also feed their chicks bones from small mammals or fish or egg shells. Larger species, such as geese and shorebirds, store calcium for eggshell formation in medullary bone, a non-structural osseous tissue that serves as a temporary storage site for calcium (Squire *et al.*, 2017). Reproductive impairment, such as egg shell thinning, has been reported in birds breeding in areas with depleted soil calcium, for example, associated with acid rain (Graveland and Drent, 1997). Most birds consume grit and other hard particles which assist in grinding and digestion of hard food items in the stomach and gizzard (especially seeds or insects), and this might also contribute to mineral balance. In many birds the bright plumages (reds, yellows, and oranges) used in sexual displays and mate choice during breeding require carotenoid pigments that are also acquired solely from the diet; stored carotenoids do not appear to be an important source of feather pigments. In some species birds which ingest food with a higher concentration of carotenoid pigments have brighter ornamental plumage or integument (Simons *et al.*, 2014). However, there appears to be little direct evidence that lack of specific nutrients in bird's diets (e.g., vitamins, minerals) routinely cause reproductive failure, with the possible exception of calcium. Nevertheless, insect prey selected by birds and occurring at high frequency in diets have higher crude protein, total fat, and mineral concentrations than insect taxa not commonly taken as prey (e.g., Razeng and Watson, 2015), suggesting birds do select prey of high nutritional quality in general.

Experimental Studies of Nutrition and Reproduction

A seemingly straightforward way to test if food availability, or specific nutrition, limits reproduction is to provide free-living birds with supplemental food before or during egg-laying, or throughout breeding. If food is a limiting factor the prediction is that food supplementation will lead to earlier laying, larger egg or clutch size, or improved breeding success because birds will be released from some nutritional or energetic constraint. Results of a very large number of such ‘food supplementation’ experiments are surprisingly mixed (Nager, 2006): 61% of 57 studies reported earlier egg-laying in supplementary fed birds compared to controls.

However, only 38% of studies also found an increase in clutch size of supplemented birds and this effect was independent of the advance in laying date in only 14 studies (28%). Finally, only 42% of studies reported larger egg size of food-supplemented females compared with controls. A meta-analysis of all such studies (Ruffino *et al.*, 2014) indicated that the mean effect size of food supplementation was significantly positive for four reproductive parameters: laying date, clutch size, chick body mass and breeding success, but that food supplementation had no detectable effect on egg size, hatching success or brood size (Fig. 2).

Where supplemental food does have a positive effect on reproductive traits the magnitude of this effect is often quite small, and food effects are modulated by environmental factors, i.e., food supplementation has little effect on bird reproduction when the background level of food abundance in the environment is high. Food supplementation advances laying date in single-brooded species by ≤ 5 days but has a greater effect on multi-brooded species (c. 15 days; Drent, 2006). Similarly, increases in clutch size (mean 0.7 eggs) and egg size (+8.1%) are small relative to natural among-female variation in these traits, and food supplementation does not reduce the marked inter-individual variation in egg or clutch size, i.e., “small-egg” females do not lay large eggs simply with access to more or better food. Rather, traits such as egg and clutch size appear to be phenotypic components of individual ‘quality’ that are relatively unaffected by food availability. Thus, while the overall positive response to food supplementation supports the idea that birds might be constrained by food for some components of reproduction the relatively modest response to food suggests there must be other factors involved (see Williams, 2012; for more discussion).

The often contradictory, and limited, outcomes of supplemental feeding experiments could be due to several factors. First, experimental diets are chosen for experimenter convenience and do not necessarily reflect the nutritional quality or composition of the bird’s natural diets. Second, it has been suggested that *specific* resources or nutrients rather than gross energy or nutrient availability might be limiting. However, providing birds with specific foods, for example, protein- lipid- or calcium-rich food, also has inconsistent effects on reproduction. In the majority of supplemental feeding experiments birds are provided with additional food weeks, and sometimes months, before the start of egg-laying and in most studies an “enormous” amount of food is supplemented (Meijer and Drent, 1999). Long-term food supplementation could provide birds with a predictive cue that might actually lead to inappropriate or maladaptive reproductive decisions. For example, urban birds have access to greater food availability than rural conspecifics, due to human-provided food, and generally lay earlier but on average clutch size, nestling mass and productivity per nesting attempt are lower in urban landscapes (Chamberlain *et al.*, 2009). Similarly, chronic supplemental feeding of blue tits advanced laying date but *decreased* clutch size and breeding success (Harrison *et al.*, 2010). This suggests that although birds can be “tricked” (Verhulst and Nilsson, 2008) into laying earlier, the response to food supplementation might be maladaptive and does not reflect ecological, evolutionary or physiologically-relevant modulation of endogenous response mechanisms.

Fig. 2 Overall effects of food supplementation on reproductive parameters of birds. Mean effect sizes (Hedges' d) and 95% confidence intervals are presented, with sample size (number of experiments) above bars. Reproduced from Ruffino, L., Salo, P., Koivisto, E., Banks, P.B., Korpimäki, E., 2014. Reproductive responses of birds to experimental food supplementation: A meta-analysis. *Frontiers in Zoology* 11, 80, with permission from Springer International Publishing.

Direct supplemental feeding of chicks can be used to test the specific hypothesis that nutrition or food availability limits chick growth and development. In fact, in many studies food-supplemented chicks do not gain more mass than control chicks (except in naturally-poor foraging conditions). This is, most likely, because supplemental feeding decreases chick begging and parents reduce their own provisioning to food-supplemented chicks. In European starlings, supplemental feeding does increase body mass prior to fledging but food-supplemented chicks show a greater pre-fledging mass recession and fledged at the same mass and body size as control chicks (Fig. 3). Furthermore, supplemental feeding does not advance developmental maturity for physiological traits (haematocrit and haemoglobin) even though chicks fledge in an immature physiological state relative to adult values (Cornell *et al.*, 2017). The long-term effects of neonatal (chick) nutrition on adult reproduction have been little studied, especially in long-lived species. In general, chick mass at fledging is positively related to survival and recruitment in birds (Schwagmeyer and Mock, 2008). However, supplemental-fed kittiwake (*Rissa tridactyla*) chicks actually had lower recruitment than control chicks, and supplemental food had no clear effect on subsequent lifetime reproductive success of fed chicks (Vincenzi *et al.*, 2015).

Nutrition and Timing of Reproduction

In almost all species breeding is restricted to a particular time of year coincident with a seasonal increase in food availability required to support demands of egg formation, incubation, and growth and development of chicks (Williams, 2012). In general, individuals that time breeding such that they have their chicks in the nest when food is most available will breed more successfully, i.e., they will have higher fitness (Perrins, 1970). Many temperate-breeding species time their breeding season to coincide with seasonal increases in abundance of specific insect species, for example, great tits (*Parus major*) feeding on winter moth caterpillars (*Operophtera brumata*) or European starlings feeding on *Tipulid* larvae (Fig. 4). Given that birds which have their chicks in the nest when food is most available will have the highest breeding success or fitness, food availability sets a selective or evolutionary value on timing of breeding, i.e., food is the “ultimate factor” explaining *why* birds have evolved to breed when they do. However, breeding requires extensive physiological and behavioral preparation before onset of egg-laying itself, which can take 6–12 weeks (at least in males). Traditionally it has therefore been assumed that food cannot act as a proximate factor, which birds would use to predict timing of breeding weeks in advance (cf. day length) since seasonal increases in food do not start early enough. However, if ovarian/oviduct development does occur only a few days before onset of egg-laying (Fig. 3; Williams, 2012) this opens up the possibility that females do respond directly to cues associated with food availability. This would be consistent with Perrins (1970, 1996) suggestion that an individual female initiates egg-laying on the date on which she is able to find enough food to form eggs “without risk to herself” (Perrins, 1970). Thus, seasonal increases in food availability might lift a constraint allowing earlier timing of reproduction in individual females sufficient to support the demands of ovary and oviduct development and egg production. Nevertheless, the physiological mechanisms linking food availability, food intake and nutritional state to the reproductive axis remain virtually unknown (see below).

Climate change has caused well-documented, but complex, shifts in timing or phenology which can vary widely among different trophic levels (e.g., plants, insects, birds). Some birds are shifting their timing of breeding at different rates (faster or slower) than

Fig. 3 Effects of food supplementation on change in body mass throughout the nestling period in European starling chicks. Chicks were not measured days 18–20. Data from Allison Cornell Pers. Comm.

Fig. 4 Timing of egg-laying, first and second broods, in relation to predicted prey (Tipulid) availability in European starlings. Prey data based on Dunnet, G.M., 1955. The breeding of the Starling *Sturnus vulgaris* in relation to its food supply. Ibis 97, 619–661.

other species in their food chain (their prey or their predators). Where advances in timing of breeding in birds lag behind that of their insect prey this will lead to phenological mismatch, i.e., breeding will no longer coincide with peak food availability, which could affect fitness and population growth (Visser *et al.*, 2012; Fig. 5). The timing and duration of seasonal increases in natural food availability also selects for variation in the number of nesting attempts each breeding season, for example, European starlings can produce two but not three broods in a year (Fig. 3). In great tits, when the first clutch is laid early relative to peak caterpillar abundance then a greater proportion of birds produce second broods (Husby *et al.*, 2009). However, neither natural variation in prey biomass or chronic food supplementation throughout breeding affects probability of second broods. Thus, food might provide a cue for breeding decisions but data are equivocal in supporting the idea of nutritional constraints on the timing of breeding or the number of breeding attempts birds make.

Fig. 5 Schematic illustration of match and mismatch between female great tits and their insect (caterpillar) prey. Image provided by Dr. Marcel Visser.

Nutrition and Reproductive Investment

It seems axiomatic that reproduction will require more resources than during non-breeding periods. Parents should need to find and consume more food to meet the elevated demands of their own reproductive activities (incubating eggs, foraging to obtain food for chicks) as well as finding additional food to provision chicks to support their growth and development. In general, birds might use different strategies to obtain resources for egg production and incubation. ‘Capital breeders’ rely on stored (endogenous) reserves accumulated prior to egg-laying and ‘income breeders’ rely on daily food intake (exogenous resources). It used to be assumed that “classic” capital breeders included migratory, Arctic-nesting shorebirds, ducks and geese, due to the short Arctic summer and limited availability of food early in the season when birds first arrive on their breeding grounds. However, even in Arctic-nesting common eider (*Somateria mollissima*) and snow geese (*Chen caerulescens*) up to 70%–80% of yolk proteins can be derived from exogenous resources, although endogenous fat reserves are more important for production of yolk lipids (~55%–80%; [Sénéchal et al., 2011](#); [Hobson et al., 2011](#)). Many smaller-bodied Arctic-nesting shorebirds also rely on exogenous resources, obtained via daily food intake, for egg production ([Klaassen et al., 2001](#)). In these species, endogenous stored reserves might be more important in allowing females to sustain incubation when there can be limited feeding opportunities. ‘Capital’ and ‘income’ therefore represent extremes on a continuum and most species likely use a mixed strategy – a balance of exogenous and endogenous resources – to meet demands of reproduction, depending on their life-history and ecological context. Most smaller-bodied birds (e.g., Passerines) and many larger-bodied birds (e.g., raptors, ducks) rely primarily on daily food intake to meet costs of egg production and incubation. During chick-rearing parents have fewer constraints on self-feeding, while finding food for their offspring, though how parents balance, and regulate, foraging for self- versus offspring remains largely unknown.

Larger-bodied breeders which rely at least to some extent on stored, endogenous reserves often produce large clutches of energy-rich eggs (e.g., waterfowl) and it has been suggested that food availability or nutrient reserves could be important in determining clutch size in ([Lack, 1967, 1968](#)). However, even for these species there is little unequivocal evidence for nutritional constraints on variation in egg or clutch size. Pre-breeding body mass or condition can be related to reproductive success in some capital-breeders, and some species (e.g., snow geese) will delay onset of egg-laying after arrival to accumulate more somatic reserves even at the expense of survival rate of juveniles ([Gauthier et al., 2003](#)). In altricial or income-breeding species, neither the number nor quality of eggs are directly related to the energetics or nutrition of the laying female. Indeed, there are good theoretical reasons why clutch size itself should *not* be nutrient-limited in species relying on daily food intake ([Arnold and Rohwer, 1991](#)). Rather, clutch size is ultimately determined by the average number of chicks for which parents can find food ([Lack, 1967, 1968](#)). Thus, in many birds, egg, clutch and brood size are likely determined not by food availability per se, but rather by the parent’s ability to forage to obtain food, and/or their physiological efficiency in converting food intake into eggs or chicks (see below).

Nutrition and Carry-Over Effects

Reproduction does not occur in isolation of other stages of bird’s life-cycles and several studies have linked feeding and nutrition on wintering areas or during pre-breeding migration to subsequent reproduction, i.e., there might be nutritional “carry-over” effects. Neo-tropical migrants using higher quality habitats in winter have higher body condition, earlier spring departure and earlier timing of arrival on their temperate-zone breeding grounds and it has been suggested this has positive effects on subsequent breeding performance. In migratory passerines and geese body condition (fat stores) during migration or at arrival on the breeding grounds can be correlated with timing of egg-laying, size and number of eggs laid, or overall reproductive success. Similarly, in seabirds earlier laying dates are correlated with pre-breeding diet quality or efficiency of foraging behaviour during the winter prior to laying ([Daunt et al., 2006](#); [Sorensen et al., 2009](#)). Nevertheless, studies where birds receive supplemental food in winter – perhaps mimicking the general public feeding garden birds – have produced mixed results, with positive, negative or no effects on subsequent reproduction (reviewed in [Crates et al., 2016](#)). A simple explanation for these results is that use of higher quality wintering or migratory habitat allows some individuals to maintain higher nutrient reserve levels which then contribute directly to reproduction. In other words, carry-over effects would reflect simple cycles of nutrient acquisition (during the non-breeding period) and utilisation (during breeding). However, few studies have directly confirmed that resource-acquisition, food availability or diet quality per se prior to breeding is what improves reproductive performance. Rather ‘high quality’ individuals might use higher quality wintering sites, occupy higher quality breeding sites, and also have higher breeding performance just by virtue of being ‘higher quality’.

Physiological and Hormonal Regulation of Food Intake and Feeding Behaviour

Mammalian studies have identified a wide range of hormonal signals that contribute to regulation of food intake, meal size, and feeding frequency, and that might explain concepts such as hunger and satiety. These include many “brain-gut” peptides, for example, ghrelin, glucagon-like peptide 1 (GLP-1) and peptide YY (PYY) released by enteroendocrine cells throughout the gastrointestinal tract, and other peripheral hormones secreted by adipocytes (leptin, adiponectin) and the pancreas (insulin, glucagon). These signals are relayed to the hypothalamus or brain stem, either humorally or via paracrine effects on vagal nerve stimulation, and integrated by anorexigenic (appetite-inhibiting) and orexigenic (appetite-stimulating) neurons in the arcuate nucleus of the hypothalamus – the melanocortin system – to regulate food intake and energy balance. In contrast to mammals, very little work

has been conducted on any of these potential regulatory mechanisms, especially in non-domesticated, free-living birds, and in relation to reproduction. Most brain-gut peptides identified in mammals have been identified in birds and most have similar inhibitory or stimulatory effects on food intake based on experimental studies, though our knowledge of this comes almost entirely from work with poultry (reviewed in [Denbow and Cline, 2015](#)). Interestingly, some hormones appear to have opposite effects, for example, ghrelin is orexigenic in mammals but anorexigenic in birds. The neuroanatomical architecture underlying central regulation of food intake and energy expenditure, and in particular the hypothalamic melanocortin system, is also well conserved between birds and mammals, although much less is known about how this system functions in birds ([Denbow and Cline, 2015](#)). There have been virtually no studies of peripheral and central hormone signalling in the context of potential changes in food intake, nutrient and energy balance during seasonal gonadal maturation, egg production, and chick-rearing in free-living birds. Plasma leptin, which might function as a “lipostat” indicating nutrient or energy status, systematically varies in free-living birds in relation to egg-production ([Kordonowy et al., 2010](#)) and chick-rearing ([Quillfeldt et al., 2009](#)). However, to date other studies of brain-gut hormones that might be involved in regulation of food intake have been restricted to other energy-demanding phases of avian life-cycles, for example, migration ([Goymann et al., 2017](#)). It is important to note that chick-rearing requires that parents find more food, to feed their chicks, but this might not represent a period of elevated food intake or hyperphagia for the parent’s themselves. Nevertheless, hormonal, metabolic and physiological regulation of food intake and energy balance during reproduction in free-living birds represents a rich field for future research.

Glossary

Heterothermy Condition where birds and mammals can change their body temperatures in a regulated manner.

Homeothermy Condition where birds and mammals maintain a single body temperature in a regulated manner.

Nomenclature

T_b Body temperature

Introduction

Mammalian reproduction and expression of torpor are often viewed as mutually incompatible processes. Reproduction typically requires acquisition of nutrients and high energy expenditure for mating behaviour and the production of young (Tyndale-Biscoe and Renfree, 1987), whereas torpor is characterised by a substantial reduction of energy expenditure by up to 90%–99% and also a fall body temperature (T_b) to between 0 and 25°C, depending on the species. Animals usually remain torpid between a few hours up to about 6 weeks (Ruf and Geiser, 2015). Birds and mammals that use torpor or hibernation and change T_b over time are called ‘heterotherms’ in contrast to ‘homeothermic’ species that maintain a constant high T_b .

To avoid the energetic incompatibility many species use a sequence of torpor followed by reproduction during the yearly cycle. In typical heterothermic rodents from the Northern Hemisphere torpor is expressed from autumn to early spring, after which reproduction commences in spring and summer (Geiser *et al.*, 2008). This pattern is especially observed in cricetid (hamsters) and sciurid (ground squirrel family) rodents (Fig. 1), which live in strongly seasonal environments with highly productive summers. These species refuse to express torpor during the reproduction season, reduce their gonads during the torpor season and even may remain homeothermic when reproductive hormones are administered.

Interestingly, not all species conform to this dogma. Torpor during the reproductive season has been observed during both pregnancy and lactation in many mammals, and also during incubation and brooding in birds (Brigham *et al.*, 2012; McKechnie and Mzilikazi, 2011; McAllan and Geiser, 2014; Geiser *et al.*, 2017). This is especially true for small mammals from the Australian arid zone, who seem to not only use torpor during reproduction, but to enable reproduction on limited resources (McAllan and Geiser, 2014). We aim to summarise available information about those mammals and birds that enter torpor during reproduction and examine the taxonomic diversity of the phenomenon.

Fig. 1 Examples of mammals that use torpor or hibernation, however the golden-mantled ground squirrel and the Djungarian hamster do not express torpor during the reproductive season. (A) Golden-mantled ground-squirrel *Callospermophilus lateralis* (Sciuridae); (B) The Djungarian hamster *Phodopus sungorus* (Cricetidae). Photos are by Fritz Geiser and cannot be reproduced without permission of Fritz Geiser.

Torpor and Reproduction in Heterothermic Birds

Birds from at least nine orders are known to be heterothermic (McKechnie and Mzilikazi, 2011; Brigham *et al.*, 2012). These include barbet relatives, kingfishers, mousebirds, swifts, hummingbirds (Fig. 2(A)), nightjar relatives, owls, pigeons and songbirds. Although heterothermy is less common in non-reproductive birds than for similarly-sized mammals (Ruf and Geiser, 2015), some use torpor while incubating eggs. For example Andean broad-tailed hummingbirds, *Selasphorus platycercus*, incubate eggs with a T_b as low as 6.5°C and in this species torpor may be as pronounced as in non-reproductive birds.

There is only one known avian hibernator, the poorwill, *Phalaenoptilus nuttallii* (Brigham *et al.*, 2012). Like many mammalian hibernators it can enter torpor for several days and drop their T_b to 5°C (Brigham *et al.*, 2012). When reproductive, few individuals reluctantly become torpid and with a cost to reproductive output (Brigham *et al.*, 2012).

Torpor and Reproduction in the Monotremes (Egg-Laying Mammals)

Echidnas (*Tachyglossus aculeatus*, Fig. 2(B)) will hibernate when non-reproductive in many areas of Australia (Morrow and Nicol, 2009). The echidnas, although having a distinct seasonal biology, also have overlapping hibernation and reproductive seasons (Morrow and Nicol, 2009). In Tasmania reproductively active males hibernate from mid-February to mid-June, while reproductively active females hibernate from early March until mid-July. Reproductive males have been found with torpid females, or with females that re-entered hibernation after mating (Morrow and Nicol, 2009). Pregnant, torpid, recently mated females also have been observed in the wild (Morrow and Nicol, 2009). Unlike other hibernators, male echidnas have enlarged testes during hibernation but not all males mate each year, and those that are not involved in reproduction continue to hibernate (Morrow and Nicol, 2009).

Fig. 2 Examples of birds and mammals that use torpor or hibernation. The blossom bat, hummingbird, feathertailed glider and echidna are all capable of using torpor or hibernation during reproduction. (A) Volcano hummingbird (*Selasphorus flammula*, Apodiformes Trochilidae). (B) Echidna *Tachyglossus aculeatus* (Monotremata). (C) Feathertailed glider *Acrobates pygmaeus* (Acrobatidae). (D) The Australian blossom bat *Syconycteris australis* (Pteropodidae). Photos are by Fritz Geiser and cannot be reproduced without permission of Fritz Geiser.

Torpor and Reproduction in Marsupials

Daily torpor and hibernation are known to occur in a number of marsupial families. Many dasyurids (carnivorous marsupials) have been observed to use torpor for most of the year, including the reproductive season. Fat-tailed dunnarts (*Sminthopsis crassicaudata*) enter daily torpor throughout the year and do so during lactation for females, and in males when testes are large and they are reproductive. Unlike many rodents, torpor patterns are similar in fat-tailed dunnarts no matter their reproductive condition (McAllan and Geiser, 2014). Pregnant stripe-faced dunnarts (*S. macroura*), can use torpor, but only in the first half of the short pregnancy. Males used torpor when reproductive hormones were present or absent, however torpor traits such as torpor bout duration, were affected by presence of testosterone in males. In females the effects of reproductive hormones on patterns of torpor use are mixed, with only the pregnancy hormone progesterone really disrupting torpor use. This contrasts to data from heterothermic rodents, where presence of testosterone abolishes the use of torpor in males, and oestrogen inhibits torpor use in females (McAllan and Geiser, 2014).

Another carnivorous marsupial the Mulgara [*Dasyurus cristicauda (blythi)*] uses daily torpor with minimum T_b around 14°C and reproduce in winter (Körtner *et al.*, 2008). Reproductively active males and pregnant females use torpor under both winter field and even mild laboratory conditions (Körtner *et al.*, 2008). Females can increase their body mass by 35% during pregnancy by frequently using torpor to conserve energy, but because neonates weigh less than 1% of the mother's body mass, it seems that females try to enhance fat storage for the more energetically demanding period of lactation, which is the main time of energy and nutrient transfer to growing young in marsupials (McAllan and Geiser, 2014). In contrast to most other mammals for which there are data, the use of torpor in mulgaras appeared to increase during pregnancy in comparison to non-reproductive individuals. However, free-ranging males displayed only shallow and brief torpor during the mating season in early winter, but after mating daily torpor was pronounced (Körtner *et al.*, 2008).

Torpor during the reproductive season also occurs in kowaris (*Dasyuroides byrnei*). Similar to the mulgaras, reproduction also influenced thermoregulation in females in the field. Pregnant female kowaries can enter torpor, but maintain high normothermic T_b 's throughout lactation in McAllan and Geiser (2014). Moreover, pregnant antechinus (*Antechinus flavipes*) enter daily torpor in captivity (Stawski and Rojas, 2016).

Torpor during reproduction also occurs in possums (diprotodont marsupials). In contrast to the dasyurids, which predominantly express torpor during pregnancy, possums appear to use torpor mainly during lactation, perhaps because their neonates are substantially larger than those of dasyurids. Feathertail gliders (*Acrobates pygmaeus*, Fig. 2(C)) undergo both short and prolonged torpor when non-reproductive with T_b falling as low as 2°C and torpor bouts lasting for up to a week in Geiser *et al.* (2008). Torpor has been observed in lactating females with pouch young in the reproductive season (Austral Spring). Similarly, free-ranging female sugar gliders (*Petaurus breviceps*), displayed daily torpor during lactation, when the pouch young were 19–34 days of age (Geiser *et al.*, 2008). During pregnancy wild female sugar gliders maintained a high and rather constant T_b , males only use torpor occasionally.

Torpor and Reproduction in the Afrotheria

The Afrotherians are often considered as basal clade in eutherian phylogeny and include elephants, sea cows, hyraxes tenrecs, golden moles, sengis, and armadillos (McKechnie and Mzilikazi, 2011). Torpor use has been described in many tenrecs. Generally these species typically have a hibernation season over the winter and can show prolonged torpor bouts from 2–4 days although more frequently the bouts are shorter are less than 24 h duration (McKechnie and Mzilikazi, 2011), whereas others may remain in shallow torpor for weeks (Lovegrove *et al.*, 2014). There is a large variability in gestation periods within each tenrec species, which is perplexing until it is noted that this phenomenon may be linked to the opportunistic use of torpor during the reproductive season, similar to marsupials. The T_b s of torpid shrew-tenrecs (*Microgale dobsoni* and *Microgale talazaci*) and large-eared tenrecs (*Geogale aurita*) are higher when females are pregnant or lactating than when they are non-pregnant and torpid (see McKechnie and Mzilikazi, 2011). Torpor was not observed during pregnancy in other tenrec species (*Hemicentetes semispinosus*, *H. nigriceps*, *Echinops telfairi*, *Setifer setosus*; see McKechnie and Mzilikazi, 2011; McAllan and Geiser, 2014). Torpor use in pregnant females appears to lengthen the gestation period (see McKechnie and Mzilikazi, 2011; McAllan and Geiser, 2014). Sengis (elephant shrews, Macroscelidea), express daily torpor or short-term hibernation when non-reproductive and exhibit seasonal torpor patterns (McKechnie and Mzilikazi, 2011). Their torpor use is adaptive to the weather conditions, as they can respond to changing conditions in spring, by returning to occasional torpor use if the weather is poor. For the sengis, the interaction between torpor use and reproduction is not clear (Lovegrove *et al.*, 2014).

Torpor and Reproduction in the Xenarthra (Anteaters, Armadillos, and Sloths)

Torpor is used by the pichi (*Zaedyus pichii*) and these temperate zone armadillos appear to have distinct non-overlapping hibernation and reproductive seasons in Ruf and Geiser (2015). However, there is one record of "hypothermia" in a pregnant three-toed sloth, (*Bradypus griseus griseus*, Morrison 1945 in McAllan and Geiser (2014)).

Torpor and Reproduction in the Eulipotyphla (Shrews, Moles and Hedgehogs)

In contrast to reports from the past, torpor has been recorded in many shrews *Crocidura russula*, *C. leucodon*, *C. suaveolens* and in *Suncus etruscus* (McAllan and Geiser, 2014). Data are scant because the very small shrews are difficult to keep in captivity and there are technological limitations for measuring their thermal physiology in the field. Data on thermoregulation of shrews during reproduction are even sparser. Hedgehogs readily use torpor both in captivity and in the wild with long torpor bouts lasting up to 27 days in some species, although 2–4 days are more usual (Dmi'el and Schwartz, 1984). In all hedgehogs studied torpor could be induced at any time of year by cool weather (Dmi'el and Schwartz, 1984). However, only one study has specifically examined the use of torpor by reproductive animals (Fowler, 1988). Pregnant European hedgehogs (*Erinaceus europaeus*) demonstrated the same daily fluctuations in T_b as non-pregnant animals, and defended their normothermic T_b only during late pregnancy (Fowler, 1988).

Torpor and Reproduction in Primates (Lemurs and Bushbabies)

Several species of primates belonging to the Cheirogaleidae (Malagasy lemurs) from five genera and in the South African lesser bushbaby (*Galago moholi*, Dausmann, 2014) all express torpor. Some of the dwarf lemurs hibernate with a distinct hibernation season, separated temporally from the reproductive season (Dausmann, 2014) and if food is scarce or the habitat is poor animals will choose not to reproduce, instead using torpor during the reproductive season (Dausmann, 2014).

In contrast the mouse-lemurs (*Microcebus* spp.) are very flexible in their use of heterothermy with some species using only daily torpor occasionally (e.g. *Microcebus berthae*, in Dausmann, 2014), whereas others showing an extended regular pattern of torpor, depending fat reserves accumulated during the active season (*M. griseorufus*, *M. murinus* in Dausmann, 2014). For the most part torpor use has not been seen in pregnant or lactating females, with most observations of torpor occurring in the “winter” (dry) period (Dausmann, 2014). The exception to this was found in *M. murinus*, in which severe food restriction in the laboratory induced torpor use in both pregnant and lactating females (Dausmann, 2014). While the experiment may seem divorced from the animals’ experiences in nature, the unpredictable environment and pronounced changes in water availability in their natural environment may require torpor use during pregnancy and lactation in wild mouse-lemurs (Dausmann, 2014). In contrast to the Madagascan lemurs, the African lesser bushbaby, *Galago moholi*, uses torpor only rarely as an emergency mechanism for energy savings, suggesting that torpor and reproduction in bushbabies are likely to be mutually exclusive (Dausmann, 2014).

Torpor and Reproduction in Bats

Many insectivorous bats (Microchiroptera) typically exhibit prolonged torpor in winter, but also short bouts of torpor during the summer reproductive season. There are many examples of bats using torpor during pregnancy and lactation (McAllan and Geiser, 2014; Stawski et al., 2014). Torpor use in reproductive bats can cause a delay in gestation in pregnant females, and a possible reduction in milk production. The main physiological disadvantage for female bats and their offspring could be that delays in parturition and embryonic and postnatal growth could result in insufficient pre-winter fattening to fuel the energy requirements during the long hibernation season in winter (Ruf and Geiser, 2015). The physiological advantage is that any transient energy shortfalls are managed such that both mother and offspring remain viable, although reproductive activities are delayed (Willis et al., 2006).

Many vespertilionid bats mate in late summer and early autumn (Stawski et al., 2014; Ruf and Geiser, 2015). After mating, sperm is stored in the oviduct and following the hibernation season, pregnancy starts immediately after fertilization. The demanding energetic costs of pregnancy and lactation continue to increase until weaning thus food consumption increases for lactating females, however female *M. lucifugus* will use torpor during pregnancy and lactation, although the bouts are shallower and shorter than in non-reproductive individuals (Stawski et al., 2014).

Torpor extends the length of pregnancy of many bats (mouse-eared bat *M. myotis*, mouse-eared bat *M. blythii*, pipistrelle *Pipistrellus pipistrellus*). Food availability coupled with cooler temperatures seems to be the main trigger for torpor use during pregnancy and lactation in these bats. In the wild this results in variable gestation lengths in animals between roost sites and over several years in the lump-nosed bat, *Corynorhinus* (= *Plecotus*) *rafinesquei* (Pearson et al., 1952). Similar to other mammals, torpor bout duration and depth was reduced in reproductive females (Stawski et al., 2014). Miniopertid bats also mate in autumn or winter, but females enter hibernation in a pregnant condition, embryonic development is delayed, and births do not occur until the following summer (Stawski et al., 2014). In the desert-dwelling Hemprich’s long-eared bats (*Otonycteris hemprichii*) torpor use occurred in pregnant female bats up to the third trimester of pregnancy, when T_b could be still lower than during normothermia, but torpor was shallower than in non-reproductive bats (Stawski et al., 2014). Shallow torpor was also expressed in lactating females, although the incidence of torpor use was reduced. In the big brown bat (*Eptesicus fuscus*), torpor has been observed during both pregnancy and lactation (Audet and Fenton, 1988; Stawski et al., 2014). Deep torpor (ie. a skin temperature drop by more than 10°C) was regularly observed during pregnancy and also during lactation.

Male *Miniopterus* also show seasonal changes in reproduction, with spermatogenesis and fertility unimpaired by hibernation use (Pearson et al., 1952). Similar to *M. schreibersii*, the vespertilionid male Daubenton’s bats (*Myotis daubentonii*) and male Bechstein’s bats (*M. bechsteinii*) also use torpor during the reproductive periods in summer, although to a lesser extent than other times of year

(Stawski *et al.*, 2014). Male big brown bats regularly used torpor throughout the year, but show a seasonal cycle in torpor use (Audet and Fenton, 1988).

The differences in torpor use between many small insectivorous bats may be because of their different roost selections. Roosting alone and in exposed roosts incurs much higher costs for maintenance of homeothermy when compared to roosting in maternity colonies in well-insulated roosts (Willis *et al.*, 2006). The importance of roost selection or thermal condition for torpor use by reproductive bats is supported by laboratory work where captive pregnant and lactating female and male long-eared bats (*Nyctophilus geoffroyi* and *N. gouldi*) studied under identical thermal conditions, showed indistinguishable thermal physiology (McAllan and Geiser, 2014). The reluctance by reproductive females to enter torpor in the field may be because of ecological rather than physiological differences, and may explain why many females roost together whereas male bats roost alone (Willis *et al.*, 2006).

Subtropical insectivorous bats also use torpor. Long-eared non-reproductive male bats (*N. bifax*) continue to use torpor no matter what the season suggesting that torpor use is beneficial throughout the year even in the subtropics (McAllan and Geiser, 2014; Ruf and Geiser, 2015). However, non-reproductive males used torpor more frequently than pregnant females during spring, similarly to male big brown bats and male Daubenton's bats (McAllan and Geiser, 2014; Stawski *et al.*, 2014). It appears that occasionally pregnant females may have been energetically constrained and therefore needed to enter torpor for short periods in McAllan and Geiser (2014).

We know less about torpor use in the Megachiroptera. The nectarivorous blossom-bat (*Syconycteris australis* Fig. 2(D)) displays daily torpor in captivity (Stawski *et al.*, 2014; Ruf and Geiser, 2015). Torpor in non-reproductive *S. australis* is used by all individuals and lasts for up to 12 h, metabolic rate falls to about 15% of resting animals and T_b drops to a minimum of about 18°C. Torpor has been observed in one of three pregnant bats, but the torpor bout of this female was shorter and the reduction of the metabolic rate was less pronounced than in most non-reproductive individuals (Stawski *et al.*, 2014). Interestingly, pregnant *R. aegyptiacus* depress their metabolism by 19% of resting metabolic rates of non-pregnant females, perhaps enabling them to spend more time on foraging or to allocate more energy to fat storage or milk production (Stawski *et al.*, 2014).

Torpor and Reproduction in Other Rodents (Dormice)

Torpor use has also been observed in several rodent families besides the sciurids and cricetids. Many species of dormice (Gliridae) use torpor (Ruf and Geiser, 2015) and use is linked to food availability, with complex relationships observed between torpor, seasonal food availability and reproduction. The hibernation cycle of the edible dormouse (*Glis glis*) is closely tied to the seasonal change, but successful reproduction is associated with seed production by beech trees (Mast years), and females may not reproduce every year (Lebl *et al.*, 2011). Because of the secretive nature of this dormouse it is unclear whether the females use torpor while in reproductive condition in the wild although being in good physical condition does not preclude their use of summer torpor (Lebl *et al.*, 2011).

Food scarcity also promotes torpor use in any season in garden dormice (*Eliomys quercinus*, in Ruf and Geiser, 2015). Torpor regularly occurs in summer in African woodland dormice (*Graphiurus murinus*, in Ruf and Geiser, 2015). Both spontaneous torpor (with food) and induced torpor (food removed) was observed in this species, although it was not stated whether the animals were reproductive, it was certainly during their reproductive season. Wild common dormice (*Muscardinus avellanarius*) hibernate for prolonged periods in winter but torpor was also observed in reproductive males and females, pregnant females, females with litters and in nestlings during the breeding season (Juškaitis, 2005). Similar to some bats, torpor bouts for pregnant females were not as deep as those found in females at other times of year (Juškaitis, 2005).

Torpor and Reproduction in the Carnivora (Bears and Badgers)

Torpor use is restricted to bears (Ursidae) and some badgers (Mustelidae). Hibernating black bears (*Ursus americanus*) and brown bears (*Ursus arctos*) show long periods of dormancy in winter and actually give birth during their hibernation period. All animals remain aware and capable of moving throughout hibernation (Tøien *et al.*, 2011). Bears do not eat, drink, defecate, or urinate during the 3–6 month hibernation period, and unlike many small hibernators, which often allow they T_b to fall near 0°C (Ruf and Geiser, 2015), their core T_b decreases to only about 30°C. Even so, because metabolic rate is very low, considerable energy savings are made over winter. Pregnancy and birth are only weakly associated with activity patterns in the brown bear (Tøien *et al.*, 2011), and circulating sex steroids have been found to be independent of torpor activity in black bears and in polar bears in McAllan and Geiser (2014).

Badgers have a hibernation season that appears independent of the reproductive season for males, and delayed embryonic implantation occurs in females, with post-implantation gestation occurring during the height of winter conditions. The European badger (*Meles meles*) will remain heterothermic when delayed implantation occurs, although in one female T_b was raised somewhat from 28.4°C before implantation to between 32.1 and 34.7°C during the remainder of the gestation period (Fowler and Racey, 1988). In males increased circulating testosterone concentrations are seasonal and begin to rise in winter, when hibernation is still common (Fowler and Racey, 1988). Similar patterns of heterothermy are seen in the American badger (*Taxidea taxus*), although T_b s have not been measured for pregnant females (McAllan and Geiser, 2014).

Discussion

Torpor use during reproduction in birds and mammals is widespread, occurring in many taxa (e.g., Monotremata, Marsupialia, Afrotheria, Eulipotyphla, Chiroptera). However, we lack information on torpor and reproduction in other mammalian groups. We clearly need more information about thermoregulatory capacities of species from several orders.

Most monotremes and marsupials have short pregnancies and the mass of an echidna egg and that of single neonates or neonate litters of marsupials is less than 0.3% of the mothers' masses (Tyndale-Biscoe and Renfree, 1987; McAllan and Geiser, 2014). Energy expenditure/day for gestation in both groups and lactation in marsupials is relatively low even over the long lactational time that they have compared to eutherians (Nicoll and Thompson, 1987). Small rodents, such as the scurids and circetids who do not have an overlap of reproduction and torpor use, have a relatively short gestation periods, heavy neonate litters (10%–65% of maternal weight) and fast development after birth and both gestation and lactation are thus energetically expensive (Nicoll and Thompson, 1987). Bats have one large neonate (13%–40% of maternal weight), but growth of fetal and young bats, as in marsupials and monotremes, is slow and energy expenditure/day during gestation is much lower than in small rodents (Nicoll and Thompson, 1987). In contrast carnivores have small altricial young with fast neonatal growth rates, but because of their size heterothermic carnivores have vastly different energetic demands than most other heterotherms.

Similarly for the birds the nightjar relatives (Caprimulgiformes) and hummingbirds (Trochiliformes) have relatively small clutch sizes and relatively long rearing periods and the additional energy expenditure required during reproduction should be small. We can conclude that mammals and birds that produce few offspring or spread the reproductive effort and the associated metabolic costs over a long time, may display torpor during the period of reproduction. The rate of development of young may be slower, but the chance of survival in offspring is unaffected because a small delay in growth within the long period of development has minimal impact.

Many of the species that use torpor during reproduction are animals from unpredictable environments, where seasonal availability of food can be cut short by abrupt weather changes. For some species the adverse weather conditions or the food shortages must be severe for induction of heterothermy (Dausmann, 2014), for others, such as bats heterothermy during pregnancy is part of the yearly cycle. For bears and badgers heterothermy during pregnancy seems part of the yearly cycle in a predictable environment, but their body size also plays an important role for carnivores. For these mammals the small extension of pregnancy or lactation may be an important strategy to optimise reproductive outcomes later in spring and summer.

Besides reproductive strategies another explanation for the differences between thermoregulatory patterns during reproduction in different mammalian groups and birds, could be diet. Abundance of most insects (and other arthropods) and nectar strongly fluctuate with season and use of torpor during reproduction may be linked to their availability. If food supply is predictable food supplies and a species can reproduce during a period of high primary productivity then strict homeothermy during reproduction will be an advantage, whereas species with relatively unpredictable food supplies may be better off using torpor when the cost is only a small extension of the reproductive period. The use of heterothermy during the reproductive season appears to be quite widespread and is a strategy for small birds and mammals to weather temporary unpredictable energetic adversities, while continuing to invest in reproduction.

REPRODUCTIVE TECHNOLOGY (NON-HUMAN/NON-PRIMATE)

Germ Cell Transplantation in Fish

Goro Yoshizaki, Tokyo University of Marine Science and Technology, Tokyo, Japan

© 2018 Elsevier Inc. All rights reserved.

Glossary

Dead end gene A type of RNA-binding protein that is specifically expressed by germ cells and crucial for primordial germ cell survival.

Donor An individual that supply germ cells used for transplantation into another individual.

Germ-line stem cells Stem cells that generate gametes.

Primordial germ cells Sexually undifferentiated germ cells that emerge in the extragonadal area and subsequently migrate to gonadal anlagen using pseudopodia.

Recipient An individual that received foreign germ cells. After germ cell transplantation, the recipient produce gametes derived from the transplanted germ cells.

Spermatogonial stem cells Stem cells that generate sperm.

Triploid Individuals carrying three sets of chromosomes; two maternal and one paternal set of chromosomes. Usually triploid fish develop normally but do not produce functional gametes due to abnormal meiosis.

Introduction

Germ cell transplantation is a method that converts immature germ cells into gametes capable of producing individual fish following fertilization. In other words, manipulation of fish germ cells has the same significance to manipulation of adult fish, making this technology useful for the fish bioengineering field (Fig. 1).

Cryopreservation of fish eggs or embryos is not possible due to their large size (approximately 0.3–8 mm in diameter) and high lipid and yolk content. Therefore, stable and reproducible methods to preserve their genetic resources were not available until very recently. The combination of cryopreservation of immature or undifferentiated germ cells (primordial germ cells (PGCs) or germ-line stem cells) and their subsequent transplantation into recipient fish is a powerful alternative to cryopreservation of fish eggs or embryos, since the transplanted germ cells undergo gametogenesis in the recipient fish gonads and eventually become functional eggs or sperm (Fig. 1(a)).

Further, germ cell transplantation can simplify the procedure to produce fish seedlings. Seedling production of large fish species, such as bluefin tuna or giant grouper requires space and is both labor-intensive and expensive. However, if their germ cells are transplanted into closely related small-bodied fish recipients, the resulting recipients, called surrogate broodstock, are able to produce gametes derived from the donor species. By doing so, seedling production of the donor-species can be simplified and performed in small facilities at lower costs and is less labor-intensive (Fig. 1(b)).

If an in vitro cultured method for donor germ cells is established, genetic modification including transgenesis and gene knockout can be easily applied to the cultured germ cells. By transplanting the resulting genetically modified germ cells into recipients, transgenic fish or knockout fish can be effectively produced in the next generation (Fig. 1(c)).

In general, donor germ cells are transplanted into sterile recipients that do not produce their own gametes. PGCs harvested from sexually undifferentiated embryos or germ-line stem cells harvested from either testes or ovaries of juveniles or adults are used as donor cells for transplantation. Unlike mammals, the ovaries of most adult fish species still carry germ-line stem cells.

Embryonic Recipients

Recipient fish used for germ cell transplantation need to be capable of nursing the donor-derived germ cells, without having their own germ cells. Otherwise, the recipient fish will produce a mixture of donor-derived and recipient-derived gametes, following transplantation. Several methods have been applied to sterilize the recipients.

First, triploidization is one of the simpler and easier methods (Okutsu *et al.*, 2007). In lower vertebrates, including fish, triploids can be easily produced by applying temperature or pressure shock to fertilized eggs. These treatments suppress the extrusion of the second polar body and produce embryos carrying three sets of chromosomes (paternal and maternal nucleus with second polar body). Noticeably, triploid fishes are viable and develop normally, although they do not produce functional gametes due to

Fig. 1 Potential applications of germ cell transplantation in the field of fish bioengineering. (a) Long-term preservation of genetic resources of endangered species. The combination of cryopreservation and xenotransplantation of germ cells from endangered species make it possible to regenerate them whenever needed. (b) Production of surrogate broodstock that can produce gametes of valuable species. Gametes of the target species can be obtained using surrogate broodstock by transplanting the germ cells of the species into xenogenic recipients. By using small-bodied and short-generation species that are easily reared, gametes of the target species can be obtained in a small facility in a short period. (c) Germ cell-mediated gene modification. If we can apply transgenesis or genome editing to the in vitro-cultured germ cells, transgenic or genome-edited fish can be produced via germ cell transplantation.

abnormal disjunction during meiosis. Triploidization efficiency in salmonid species is nearly 100% and as good quality eggs are used, survival rates are not sacrificed. Further, triploidization is easy to apply to large-scale production. However, it is difficult to produce 100% triploid populations in most pelagic fish species that produce small eggs. Although it is easy to perform triploidization treatment, especially with temperature shock, one theoretical problem is that triploid gonads have relatively large numbers of mitotic germ cells (prior to entering meiosis) to occupy the germ cell niche (see below).

A second option is the knockdown of genes that are essential for survival or for normal migration of PGCs (Saito *et al.*, 2008; Yoshizaki *et al.*, 2016). In the case of fish, gene knockdown can be effectively performed by microinjection of antisense morpholino oligonucleotides against the DNA region around the start codon of the target gene into fertilized eggs prior to the first cleavage. Among the many genes that are related to germ cell development, *dead end* (*dnd*) is widely used since its effects are specific to germ cells and the resulting knockdown fish do not show any malformation other than their gonads lack endogenous germ cells. Without endogenous germ cells, the *dnd* knockdown recipients avoid competition between endogenous and donor-derived (transplanted) germ cells for the germ cell niche. This is an advantage over using triploidization. Although delivering antisense morpholino oligonucleotides into individual eggs is both labor intensive and time consuming.

Recently, germ cell-free fish were produced by knockout of the *dnd* gene using artificial nucleases such as CRISPR/Cas9 (Wargelius *et al.*, 2016). This strategy requires producing founder mutants by microinjection into their fertilized eggs. This mutant strain can be maintained as heterozygous mutants (since homozygous mutants are sterile) by mating heterozygous males and females. One fourth of the resulting offspring are homozygous mutants, namely germ cell-free fish, making this an attractive option to produce recipients for germ cell transplantation.

Transplantation of PGCs into Embryos or Hatchlings

In any animal species, including fishes, PGCs emerge in the extra-gonadal area and then migrate to the gonads, partly through chemotaxis. The gonadal anlagen secrete a chemokine, CXCL12, known as stromal cell-derived factor 1 (SDF-1) and PGCs express its receptor, CXCR4. The PGCs migrate by the guidance of CXCL12. If migrating-stage PGCs are isolated and transplanted into the blastodisc of blastula embryos, they migrate to the recipient gonads where they begin gametogenesis (Giraldez *et al.*, 2005; Fig. 2(A)). Alternatively, PGCs can be isolated from the gonadal anlagen immediately after they have completed migration, and transplanted into the body cavity of newly hatched embryos (Fig. 2(B)). The transplanted PGCs migrate to the recipient gonads and resume gametogenesis (Takeuchi *et al.*, 2003). A micromanipulator under a binocular dissection microscope can be used for such transplantations. In either case, if the recipient is male the donor-derived PGCs differentiate into functional sperm and into

Fig. 2 Methods to transplant germ cells into recipients. (A) Transplantation of migrating PGCs into blastulae embryos. Germ cell-free recipients produced by knock down of the *dead end* gene are used. (B) Transplantation of post-migratory PGCs into the body cavity of hatchlings. Triploid recipients are used. (C) Transplantation of germ-line stem cells into the body cavity of hatchlings. Triploid or germ cell-free recipients produced by knock down of the *dead end* gene are used. (D) Transplantation of spermatogonial stem cells into the testes of adult recipients. Recipients with depleted numbers of germ cells following busulfan-treatment are used.

eggs if the recipient is female, regardless of the sex of donor PGCs. Although obtaining large numbers of PGCs is difficult, only a few PGCs (from one to ten) are needed for each recipient. Noticeably, in zebrafish even single PGC transplantation results in recipients able to produce donor-derived gametes (Saito *et al.*, 2008). It is notable that migrating PGCs isolated from early embryos cannot be used for intraperitoneal transplantation. In addition, gonadal (post-migratory) PGCs from gonadal anlagen cannot be used for transplantation into blastula recipients. In both cases, the donor-derived PGCs are unable to migrate to the recipient gonads appropriately.

This type of PGC transplantation (transplantation into blastula embryos and hatchlings) can be applied to interspecies transplantation (xenotransplantation) (Takeuchi *et al.*, 2004; Saito *et al.*, 2008). The resulting gametes produced by the xenogeneic recipients are functional with viable offspring. It has been reported that pearl danio (*Danio albolineatus*) eggs and sperm, were successfully produced using germ cell-free zebrafish (*Danio rerio*) recipients through knockdown of the *dnd* gene. On the other hand, the recipient zebrafish could produce sperm of goldfish (*Carassius auratus*) and loach (*Misgurnus anguillicaudatus*), but not their eggs (Saito *et al.*, 2008). Thus, production of donor-derived eggs is more difficult than that of donor-derived sperm and requires closely related recipient species. The transplanted allogeneic or xenogeneic germ cells were not immune rejected since the donor-derived germ cells were transplanted into recipient embryos before they acquired a mature immune system. The recipient may have acquired immune tolerance following transplantation of certain amounts of foreign cells.

It has been reported that gonadal anlagen of rainbow trout right after the PGCS completed migration and zebrafish embryos carrying migrating stage PGCs can be cryopreserved by slow-freezing (Kobayashi *et al.*, 2007) or vitrification (Higaki *et al.*, 2010) respectively. Further, these PGCs can be used for the transplantation methods discussed above. These methodologies are powerful techniques for the long-term storage of fish genetic resources, since the resulting recipients produced functional egg and sperm.

Germ-Line Stem Cell Transplantation into Hatchlings

As is the case with PGC transplantation, mitotic germ cells retrieved from juvenile or adult testes or ovaries, can be used for transplantation. When whole testicular or ovarian cell suspensions are transplanted into body cavities of newly hatched embryos, some of the mitotic germ cells within the gonadal cell suspension migrated towards the recipient genital ridges where they eventually incorporated. The transplanted germ cells began spermatogenesis or oogenesis when they were transplanted into

male or female recipients respectively. The resulting recipients produced functional eggs or sperm, depending on the sex of the recipients (Okutsu *et al.*, 2006; Yoshizaki *et al.*, 2010; Fig. 2(C)). Thus, the sex of the germ cells, are plastic, controlled mainly by somatic environments, rather than germ cell autonomy. Further, the recipient fish can produce large numbers of donor-derived gametes (rainbow trout recipients produce approximately one billion sperm in a spawning season) for several spawning seasons (Okutsu *et al.*, 2006). Thus, the donor-derived germ cells incorporated into recipient gonads can produce large numbers of gametes for several spawning seasons, suggesting they can both self-renew and differentiate. Thus, only germ-line stem cells (either spermatogonial stem cells or oogonial stem cells) that were included in the gonadal cell suspension incorporated into recipient gonads and resumed gametogenesis. This transplantation method was first established in Salmonidae species and recently applied to many other species, including Carangidae, Scianidae, Tetraodontidae, Cichlidae, Cyprinidae and Adrianichthyidae and it was confirmed that they all produced donor-derived gametes.

Xenotransplantation is also possible using germ-line stem cells as donor cells (although whole gonadal cell suspensions are usually used as donor cells, this transplantation is called germ-line stem cell transplantation hereinafter). To date, triploid masu salmon (*Oncorhynchus masou*) broodstock producing only donor-derived rainbow trout (*Oncorhynchus mykiss*) eggs or sperm have been produced through germ-line stem cell transplantation (Okutsu *et al.*, 2007). Further, by mating male and female recipient salmon, all donor-derived rainbow trout offspring were produced for at least three consecutive spawning seasons, using masu salmon as parents. In addition, viable tiger puffer (*Takifugu rubripes*) offspring were produced using surrogate triploid grass puffer (*Takifugu niphobles*) parents. In this case, the donor tiger puffer required at least two and three years to mature into adult males and females respectively. However, the recipient grass puffer produced tiger puffer gametes in 11 months and two years in males and females, respectively. Thus, germ-line stem cell transplantation can shorten the generation time and accelerate breeding processes that usually require several generations.

Cryopreservation of Germ-Line Stem Cells

Whilst cryopreservation of germ-line stem cells is possible, cryopreservation of whole testes or ovaries without dissociation is more frequently used for practical purposes, since the handling of whole gonads is easier than dissociated gonadal cell suspensions (Lee *et al.*, 2013, 2016). The germ-line stem cells retrieved from cryopreserved testes or ovaries can be used for intraperitoneal transplantation using the same method that was developed using freshly isolated germ-line stem cells. The resulting female and male recipients successfully produced functional eggs and sperm. Using this method, gametes can be produced from germ-line stem cells retrieved from cryopreserved testes or ovaries; easily harvested from juvenile to adult fish. When considering practical applications, this is the advantage of this method compared with using PGCs, since PGC cryopreservation always requires embryos with migrating PGCs or gonadal anlagen containing post-migratory PGCs. Therefore, when long-term preservation of farmed fish (their whole life-cycle is managed in captivity) is needed, both cryopreservation of PGCs or germ-line stem cells are options. However, in the case of endangered species, cryopreservation of the germ-line stem cells is the only realistic option, since isolating embryos from endangered fish species would be difficult. Since cryopreservation of fish eggs or embryos are still not possible, this combination of germ cell cryopreservation and their transplantation is a powerful tool to preserve genetic resources of endangered fish species. It is advisable to use testes, as the donor material for germ-line stem cell transplantation, since they contain more transplantable germ-line stem cells compared with ovaries. Approximately 500–10,000 type-A spermatogonia are needed for one recipient individual, resulting in 20%–80% of recipients producing donor-derived gametes, although this varies dependant on species. In the case of rainbow trout, juvenile trout (approximately 10 cm in body length) can supply approximately one million of type-A spermatogonia and this is not a limiting step.

Germ Cell Transplantation into Adult Recipients

In the previous sections, donor-germ cells are transplanted into embryos or hatchlings whose immune systems are still immature, although spermatogonial transplantation into adult gonads is also possible (Lacerda *et al.*, 2010; Majhi *et al.*, 2009; Fig. 2(D)). In these studies the endogenous germ cells of recipients was removed by treatment with busulfan, a type of alkylating agent. The donor testicular cell suspension, which contained spermatogonial stem cells, was transplanted into recipient gonads via the urogenital pore or a surgical procedure. As in the case of germ-line stem cell transplantation mentioned above, it has been predicted that only the spermatogonial stem cells can colonize the recipient gonads and undergo gametogenesis. This method does not require micromanipulation and seedling production processes. Further, the time period required to obtain donor-derived gametes is relatively short. However, it requires large numbers of donor testicular cells (10^6 – 10^7 , dependant on the target species). When considering real applications to conservation of endangered species, the supply of donor cells will be a limitation. Recently, protocols to propagate in vitro spermatogonial stem cells from several species have been reported. This is a solution to generate large numbers of donor cells from small donor individuals. Theoretically this technology cannot be applied to species whose ovary lacks an ovarian capsule, called gymnovarian or semi-gymnovarian. To date, this type of germ cell transplantation has been performed in tilapia (*Oreochromis niloticus*), pejerrey (*Odontesthes bonariensis*) and zebrafish. However, donor-derived eggs were only obtained in the pejerrey. In addition, transplantation of cryo-preserved spermatogonial stem cells produced functional sperm (Lacerda *et al.*, 2010).

As mentioned above, each method has both advantages and disadvantages. Therefore, selection of the right method for each purpose is important. Although several potential applications of these technologies are introduced in this article, there are more applications that can be applied to fish bioengineering field.

Glossary

Cryoprotecting agents or CPAs Cryoprotecting agents or CPAs are chemical compounds which need to have some specific properties as high solubility in water even at low temperatures, present low toxicity, and depress the freezing point of a solution (Mazur, 1970, 1977, 1980, 2004; Muldrew *et al.*, 2004). CPAs can be classified according to their molecular weight as permeating cryoprotectants – those with low molecular weight, which can permeate through biological membranes-, and non-permeating cryoprotectants – those with high molecular weight, which, therefore, cannot permeate through the membranes. The most used CPAs are: dimethyl sulfoxide (Me2SO), ethylene glycol (EG), propylene glycol (PG), trehalose (TRE), sucrose (SUC) and polyvinyl pyrrolidone (PVP).

Introduction

The term Cryobiology was originally coined by Sir Alan Parkes, defined as the study of “frosty life” in 1964. Cryopreservation consists on freezing, banking and thawing living organisms, cells or tissues in the presence of cryoprotecting agents (CPAs) (Mazur, 2004). This is a well-developed and worldwide recognized technique for achieving long-term preservation and storage of biological material at low temperatures. The preservation of biological material in a stabilized stage over time is an essential need for both basic and applied sciences in different research areas (Mazur, 2004; Pegg, 2007).

Despite the studies in the field it was not until 1972 when Mazur, Leibo and Whittingham (independently and simultaneously with Wilmut and Rowson) reported a scientific landmark event: the first ever live mouse pups born from cryopreserved embryos making the startpoint for the development of cryopreservation protocols for gametes of livestock for commercial purposes. The development of the science soon broaden with applications in human reproduction, conservation or aquaculture. The first reported livestock animal born from a cryopreservation procedure was a calf at Wilmut and Rowson laboratory in 1973. Sperm cryopreservation in fish was first reported more than 50 years ago (Blaxter, 1953) and the first marine invertebrate gametes cryopreserved were sea urchin sperm by Lanan (1971) on oyster sperm and Asahina and Takahashi (1977) (Figs. 1 and 2).

Fig. 1 Summary of important core events in the history of Cryobiology. References for the main papers related to those event are listed in the bibliography (Crowe *et al.*, 1985; Fahy *et al.*, 1984; Lovelock, 1953, 1954; Lovelock and Bishop, 1959; Luyet and Keane, 1952; Luyet and Geherio, 1940; Mazur, 1963; Polge *et al.*, 1949; Swanson *et al.*, 2007; Toledo *et al.*, 1989; Whittingham *et al.*, 1972; Wilmut, 1972; Wilmut and Rowson, 1973).

Fig. 2 Numbers of published papers per decade in the topic of Cryopreservation as a scientific area has grown steadily over the years (right), a focussed view on a smaller area of cryobiology as marine invertebrate cryopreservation, shows the same trend, the number of published papers (right) shows also an increase. Data obtained from PubMed And Scopus.

The aims of cryopreservation are very clear: to develop methods to preserve biological material structurally and functionally as intact as possible for future use. The range of uses is very wide, medical, species conservation and stock management,

Preservation of fundamental model organisms germplasm like mice (Critser and Mobraaten, 2000; Nakagata, 2000) and zebrafish (Hagedorn *et al.*, 1998; Zhang and Rawson, 1996; Khosla *et al.*, 2017) that will help maintain the different transgenic breeds securely whilst reducing the costs of time, space and cost of life breeding of all these lines along time.

Cryopreservation can be a very powerful biotechnological tool for aquaculture production, i.e. for fisheries conservation and wild stock enhancement (Zhang, 2004), for the production of all year-round spat supply without the need to condition broodstock (Adams *et al.*, 2011a,b) and for the improvement of selective breeding programs management (Adams *et al.*, 2011a,b; Zhang, 2004).

Principles of Cryopreservation

When cells are exposed to a solution containing a CPA, the differences in the osmotic pressure of the solution inside and outside the cell will cause an initial diffusion of water from the cell to equilibrate the osmotic pressures. At the same time, the higher concentration of the CPA in the external solution will cause the diffusion of the CPA into the cell. The process will stop once the concentration of the CPA equalize outside and inside the cell (Pegg, 2007) (Fig. 3).

The freezing point of the external solution is dependent on the solution media and the CPAs present. Once the cooling starts the external media will freeze before the cells and water inside will be under its thermodynamic freezing point. Water below its freezing point is defined as supercooled and has higher vapour pressure at a given temperature than the ice outside the cell (Dennison *et al.*, 2000; Mazur, 2004). As long as this difference in potential remains, water will slowly leave the cell and freeze externally and the cell will dehydrate. The dehydration will cause the concentration of solutes inside the cell to increase and the potential is reduced to reach the thermodynamic equilibrium and the cell will freeze without the formation of internal ice crystals which would be lethal (Fig. 2).

Fig. 3 Schematic representation of the most important physical-chemical processes during slow cooling cryopreservation. Modified from: Figure 1. Mechanisms of cryoinjury in living cells. Doyong Gao, Critser, J.K., 2000. ILAR Journal 41 (4), 187–196.

When cooling, the cell will slowly dehydrate due to the differences in water vapour pressure inside and outside the cell. If cells are cooled too slow, the cell would dehydrate too much, the concentration of internal solutes would increase and the whole process would cause irreparable damage to the cell that would not recover cell structure and functions afterwards. On the contrary, if cells are cooled too fast, water does not leave the cell becoming increasingly supercooled and when the Intracellular nucleation temperature is reached, the water will freeze internally. Optimal cooling rates are cell and species specific. Factors like membrane permeability, cell size or cell shape will determine the optimal cooling rate.

The cryopreserved cells or embryos will need to be stored in liquid nitrogen (-196°C) to ensure the conservation for as long as necessary (Leung, 1991; Leibo and Songssassen, 2002). At this low temperature no chemical reactions take place and cellular metabolism is on hold. Once cells are stored in liquid nitrogen their viability would only be affected by background radiation- which at normal level will take 2000 years to become a hazard to stored cells (Glenister *et al.*, 1984; Fig. 4).

Sperm Cryopreservation

Since Polge *et al.* (1949) discovered quite by accident the cryoprotective role of glycerol while working of the cryopreservation of sperm, sperm cryopreservation protocols have been developed more or less successfully for many organisms like Fish (Kopeika *et al.*, 2007; Cabrita *et al.*, 2010), mice (Jin and Mazur, 2015), marine invertebrates (Tiersch and Mazik, 2011; Adams *et al.*, 2004; Liu *et al.*, 2014), livestock (Curry, 2000), endangered wild animals (Fickel *et al.*, 2007). Sperm in general is easy to cryopreserve by slow cooling with the minimum handling possible because it is very sensitive to factors like handling, osmotic changes and drastic changes in temperature (Walters *et al.*, 2009). Sperm cryopreservation usually leads to reduced motility and therefore fertilization capability, in most cases the solution for increasing fertility is to increase the egg: sperm ratio carefully. Cryopreserved sperm can show reduced binding capacity and/or morphological changes that will also affect fertility, in these cases methodologies like Intracytoplasmic Sperm Injection (ICSI) might be the solution (Fig. 5).

Fig. 4 The cooling rate is one of the factors that will determine if the cell can dehydrate at the right pace, following equilibrium (EQ). If the cooling rate is too fast, the volume of cell water will be too high and Lethal Internal Ice Formation (IIF) will take place. Cell size and shape, the volume of intracellular water, membrane composition and permeability are other factors which play a part in the movement of water and cryoprotectants in and out of the cell during cryopreservation. Figure from Mazur, P., Seki, S. Pinn, I.L., Kleinhans, F.K., Edashigue, K., 2005. Extra and Intra-cellular ice formation in mouse oocytes. *Cryobiology* 51(1), 29–63.

Fig. 5 ICR Mice sperm showing irreversible altered morphologies and membrane fusion (either curved sperm, which can be considered as a light distortion or sperm with a knot/hairpin shape, which is an extreme distortion) due to dehydration by exposure to 2M Sucrose for 2 min. Mice sperm total length is around 122 μm .

Developed sperm cryopreservation for model organisms: mice, primates, freshwater and marine fish, marine invertebrates.

Oocyte Cryopreservation

Oocyte cryopreservation had been a complicated task. In general, less work has been carried out with oocytes due to their chilling-sensitivity and their large yolk content. There are no published protocols with more than a symbolic survival described for fish oocytes or marine invertebrate oocytes for example. Mammals are the exception. The reason for these differences in survival between species to cryopreservation can be explained by the study of several factors: oocyte size, membrane composition, membrane permeability and % of yolk and water. Lipid content of oocytes and embryos is an important parameter linked to both quality and cryotolerance. Physical changes of lipids submitted to freezing temperatures are among the major causes of cellular cryodamages (Pereira and Marques, 2008).

Developed oocyte cryopreservation for model organisms: mice, primates.

Embryo and Larvae Cryopreservation

Cryopreservation of embryos and larvae as an alternative to oocyte cryopreservation have given more promising results in many cases, in special within the marine environment (Asahina and Takahashi, 1979; Olive and Wang, 1997; Toledo *et al.*, 1989; Grout and McFadden, 1991; Lin *et al.*, 1999; Wang *et al.*, 2011; Paredes *et al.*, 2015) but the cryopreservation of more developed stages brings also new challenges. Both oocytes and embryos show high sensitivity to sub-zero temperatures, sensitivity to CPA exposure and lower permeability than sperm, embryos and larvae present sometimes very complex membrane systems and compartments that complicate CPA and water transportation (Fig. 6).

Developed embryo/larvae cryopreservation for model organisms: mice, primates, drosophila (Mazur *et al.*, 1992), marine invertebrates.

Future Lines of Research

Fundamental and hypothesis driven research will continue to increase in cryopreservation helping us understand all the steps and crucial points of the process. More research is needed in order to optimize and standardize cryopreservation procedures for many organism's gametes. The answers about lethal and sub lethal cryoinjuries related to cryopreservation would probably require a molecular point of view. The understanding of how metabolism standby happens and, more importantly, what happens after thawing at the molecular level, will help us to understand organogenesis and cryoinjuries that could be responsible for the damage of those cells that could not survive after cryopreservation or show non-lethal cryoinjuries.

We still lack of basic information about membrane permeability and osmotic tolerances of different cells and species. There will be a movement from classical cryoprotectants like Me₂SO or Gly towards the use of antifreeze proteins from freezing tolerant organisms or engineered CPAs with less toxicity and higher membrane permeability, this line of research would be specifically interesting for organism's cell types/species which manifest high sensitivity to CPA exposure.

Sperm cryopreservation still has to address the issue of post-thawing sperm damage, both the causes and possible minimization that will increase sperm performance and therefore fewer spermatozoa will be needed per fertilization round. Oocytes have proven to be more difficult to cryopreserve than other cellular types, and despite numerous trials and promising results, the oocyte cryopreservation of several organisms will continue to be a very active research line, specifically due to their chilling sensitivity. Embryos and larvae will continue be studied focusing attention on cryoinjuries, like growth and morphology modifications, activity post thawing and low larval development in order to increase long term survival.

In special, vitrification will be profusely addressed for all species and cell types within the next decade, and vitrification procedures and mechanisms will continue to develop and increase survival, this will be very important for chilling-sensitive cells as oocytes and embryos.

Vitrification involves converting water into a non-crystalline or amorphous glass. To achieve this conversion, the initial view has been that cells have to be immersed in solutions containing a very high concentration of glass-inducing solutes (typically ≥ 6 molal) which was highly toxic and in general, they have to be cooled very rapidly (typically $\geq 50,000^\circ\text{C}/\text{min}$). The belief that rapid cooling was essential meant that the volumes of cell suspensions being cooled had to be very small and the carriers or containers had to have very small masses (Kuwayama, 2005). Fahy, 1987, Boutron and Mehl, 1990, later the Mazur's group (Seki and Mazur, 2008 and, 2009) or even more recently (Papatheodorou *et al.*, 2013; Panagiotidis *et al.*, 2013; Schiewe *et al.*, 2015) that studied and compared survivals using open and closed vitrification devices, reported that the high survivals reported were due to the rapid warming of those samples and not the fast cooling.

The especially high sensitivity to warming rate found, strongly suggests that the lethality of slow warming is either a consequence of the crystallization of intracellular glassy water during warming or the growth of small intracellular crystals formed during cooling by their recrystallization during slow warming (Mazur and Seki, 2011).

Recent work in vitrification and fast rewarming had led to the reporting of interesting advances in the cryopreservation of important model species. Seki *et al.* (2014) and Jin and Mazur (2015) have reported that when the vitrification solution contains only the non-permeating solute (sucrose), survivals after vitrification and laser-induced ultra-rapid warming are also about 90% for

Fig. 6 Cover of Science from October 1972 reporting on the cryopreservation of mice embryos for the First time by Whittingham, Leibo and Mazur. The cryopreserved and thawed embryos were later implanted and in the picture you can see the recipient mother and the pups born from the cryopreserved embryos.

mice embryos and oocytes. Paredes (2016) reported the high survivals of yeast also using the same methodology. Khosla *et al.* (2017) reported the vitrification and fast rewarming of Zebrafish embryos that survived up to 5 days post-vitrification using gold nanoparticles heated by a laser in order to achieve high warming temperatures. More advances will be produced by the use of these methods in the following years.

Reproductive Cloning

Reproductive Cloning

The goal of reproductive cloning is to produce one or more genetically identical animals that carry the same genetic makeup (genotype). Many examples of genetically identical offspring can be found in nature and range from monozygotic (identical) twins in humans to the seven-banded armadillo that can produce up to 15 genetically identical pups in a single litter. These identical animals are formed from the division of a single embryo into two or more parts, each of which can develop into a fully formed individual. Although these animals are genetically identical, they are technically not considered clones as they result from an embryo produced sexually (the combination of the genetic material of a sperm and egg) that somehow splits into several embryos during development. Reproductive cloning involves the production of genetically identical animals by employing a specific technology developed by scientists, nuclear transplantation.

In its simplest form, nuclear transplantation refers to the transfer of the nucleus (chromosomes/DNA) of one cell into another. The utilization of this technique to produce cloned animals involves transferring the nucleus of a single cell derived from the animal being cloned (cell donor), into an unfertilized oocyte collected from a female (preferably from the same animal species), and that has had its own DNA removed (enucleated oocyte). When this happens, components contained within the cytoplasm of the enucleated oocyte have the ability to reprogram the donated nucleus such that it resets the developmental clock back to the one-cell stage of development, similar to an egg just after fertilization by a sperm cell, prior to the first cell division. If successful, the reconstructed embryo derived from this process will begin to develop and can be transferred into the reproductive tract of a surrogate mother where it will develop to term and result in an animal with the same genetic traits as the cell donor (Figs. 1 and 2.)

Historical Overview

The idea of developing methods to produce, and reproduce genetically identical animals, has been around since the early 1900s. Hans Spemann, often referred to as the “father of cloning”, performed extraordinary studies involving nuclear transplantation using cells derived from developing salamander embryos, resulting in the production of genetically identical offspring. He later referred to a “fantastical experiment” in his book, *Embryonic Development and Induction* (1938), where he outlined the process of nuclear transplantation, and described the basic methodology still used today to clone animals (Speman, 1938).

At the time Spemann described this procedure, the methodology and equipment needed to perform such a difficult task were not available. Therefore, it was not until the early 1950s that Robert Briggs and Thomas King were able to perform such experiments. Using a small glass pipet they removed the DNA from a *Rana pipiens* egg, replaced it with the nucleus from a blastula stage embryo, and demonstrated that cloned frogs could be produced by transferring nuclei obtained from early stage embryos into enucleated oocytes (Briggs and King, 1952).

Fig. 1 Reproductive cloning by nuclear transplantation.

Fig. 2 Reproductive cloning by nuclear transplantation.

It is important to note that cells utilized for cloning in these early experiments were derived from growing embryos rather than adult animals. The dogma at that time was embryonic cells could be used for cloning because the cells had not yet differentiated into a specific cell type and thus remained totipotent and capable of developing into any tissue in the body. However, a major breakthrough, supporting the idea that nuclear transplantation could potentially be utilized to clone adult animals using cells that were more differentiated came in 1962 when John Gurdon reported the utilization of nuclear transfer to produce cloned frogs using cells obtained from the gut of feeding tadpoles. The transferred nucleus in these experiments had originated from cells that had clearly differentiated into a somatic cell type and thus dispelled the prevailing theory that nuclei were incapable of directing development after differentiation. The importance of this work was recognized by Gurdon being awarded a Nobel Prize in 2012 ([Gurdon, 1962](#)).

While work with amphibians was being carried out in the early and mid-1900s, it was not until the late 1970s that any significant work involving the utilization of nuclear transfer to try and clone mammals was performed. This was likely due to the much smaller size of mammalian eggs compared to amphibians, limitations in the equipment and difficulties with adapting the technology to other species. Procedures had to be developed that would allow micromanipulation of individual cells, ova and embryos in addition to the expertise needed to transfer cloned embryos into the reproductive tract of the appropriate surrogate mother. Moreover, simply obtaining large numbers of oocytes from mammals that could be utilized for experiments involving nuclear transfer was in itself a challenge.

The great majority of early work with nuclear transfer in mammals involved the manipulation of ova and embryos derived from mice. Peter Hoppe and Karl Illmensee reported the successful production of cloned mice by transferring cells derived from the inner cell mass of a developing embryo into enucleated zygotes, then transferring the cloned embryos into recipient females ([Illmensee and Hoppe, 1981](#)). However, many attempts by other laboratory groups failed to repeat this work; and in 1984 Jim McGrath and Davor Solter published the results of their research stating that “cloning mammals by simple nuclear transfer was biologically impossible” ([McGrath and Solter, 1984](#)). Solter, McGrath and other scientists working with mice at that time, again thought the problem was related to embryonic differentiation. In spite of the experiments performed previously by Gurdon that demonstrated differentiated cells could be used for cloning frogs. Researchers working with mice hypothesized that in mammals, as embryonic cells became more differentiated, they could not be used for cloning. McGrath and Solter were successful at producing cloned mice by nuclear transplantation when 2-cell embryos were used as nucleus donors, but not when nuclei were derived from the 4-cell stage or beyond. In mice, the 2-cell stage of development represents the time at which the embryonic genome is activated; in other words, the first time in mouse development when cells actually begin to use their own genes to transcribe mRNA, produce new protein and differentiate into unique cell types.

Early work in other mammalian species continued to support the idea that differentiated cells sequentially lose the ability to regain totipotency following nuclear transfer. Steen Willadsen reported the successful cloning of sheep, and then cattle, using 8–16 cell embryos as nuclei donors ([Willadsen, 1986](#)). In terms of development, this is similar to mice, as maternal/zygotic transition, the time point in development when an embryo starts producing its own mRNA and protein (embryonic genome activation), begins at the 2-cell stage in mice and the 8–16 cell stage in sheep and cattle.

Willadsen’s work with cattle, a species with substantial economic value, no doubt played the major role in efforts to move cloning from the research laboratory to commercial application. The initial business model was based on cloning to propagate (replicate) cattle representing the top 5%–10% in terms of phenotypic performance. If cloning could be used to increase the number of animals representing genetics of the top producers, large increases could be made in the efficiency of milk and meat production.

In the late 1980s, Willadsen moved from England to the United States to work for Granada Genetics Inc., and commercialize cloning in cattle. His efforts proved extremely successful, however, he left Granada after only about a year and took his talents

to Canada where he started a similar program focused on cloning cattle for Alta Genetics. Granada, Alta, and shortly thereafter American Breeders Services (ABS) represented the first 3 commercial entities in the world to offer commercial cloning to the cattle industry.

Early on, this approach proved to be viable, and a large number of cloned cattle were produced for various cattle producers. However, a number of unanticipated problems also occurred, and the dream of producing large numbers of cloned livestock representing the top individuals of beef or dairy cattle and utilized for the production of food and fibre never materialized. A major problem that interfered with the large scale production of clones was founded in the inefficiency of nuclear transfer when measured by the actual number of live offspring produced. Regardless of the countless experiments that were conducted to try and improve the process, the great majority of embryos produced by nuclear transfer failed to result in a viable pregnancy and/or a normal calf. This problem could be overcome by simply producing and transferring more cloned embryos. However, it soon became clear that in most cases, the costs far outweighed the benefits. Only 10%–20% of embryos produced by nuclear transplantation resulted in a viable pregnancy. In addition, another serious and unexpected problem was that a significant number (approximately 30%) of the offspring born as a result of cloning exhibited abnormal development, most notably, large birth weights associated with placental anomalies. It was not uncommon to see calves born weighing almost 2 X normal, which caused significant health problems at birth for both the calf and surrogate mothers (Wilson *et al.*, 1993). As a result, all recipient cows carrying cloned pregnancies had to be carefully monitored and many needed assistance at birth. This was simply unacceptable to the cattle industry. A final issue that also clearly played a major role in the failure to adopt cloning to produce large numbers of high-producing cattle was the unexpected observation that even though the animals were genetically identical, clones could exhibit remarkable differences in their phenotypes. As mentioned above, this first became obvious when looking at birth weights and the enormous variation that resulted. However, as more cloned animals were born, including not only cattle but sheep, goats, pigs, horses, etc., it was clear that while the genotypes were identical, the phenotypes were not. The cause of this was not clear and remains uncertain even today. However, obvious culprits include the environment in which fetal development occurs and unexplained differences in nuclear reprogramming within the oocyte needed to support normal development. In addition, since cloned animals were derived using enucleated oocytes collected from other animals, the possibility existed that the mitochondria which are exclusively inherited through the cytoplasm of the ova were also having an effect on the final phenotype.

Although various problems with producing cloned livestock using cells derived from early stage embryos prevented the large scale utilization of this technology for production agriculture, other potential applications continued to drive the research and development of cloning. The primary interest changed from using the technology to produce large numbers of genetically identical animals to producing a few, or even “one” animal representing for example, a genotype that was extremely rare or had been lost (i.e., unique animals of extremely high value that had died or were close to death, endangered and extinct animal species). Although clones did not always exhibit similar phenotypes, their genotypes were identical, therefore clones were extremely useful for breeding, thus a powerful tool that could be used for the conservation and/or propagation of a particular genotype. The other driving force was founded in the utilization of cloning as a potential tool for producing genetically modified animals. However, both of these applications required methods that would allow the utilization of genetically identical cells that had differentiated beyond embryonic, and which could be expanded in culture to obtain large numbers of cells.

One of the first key experiments which provided strong support for addressing this challenge and test the hypothesis that differentiated cells could be reprogrammed by nuclear transplantation and used to produce cloned animals was reported by Sims and First in 1994 and again by Campbell *et al.* (1996). Sims and First derived cell lines from the inner cell mass of a blastocyst stage bovine embryo and cultured these cells using methods and conditions designed to expand the cell population while at the same time maintain pluripotency (Sims and First, 1994). Campbell *et al.* utilized the embryonic disc of a sheep embryo that during culture differentiated to an epithelial type cell (Campbell *et al.*, 1996). In both cases, nuclear transfer to an enucleated oocyte produced live offspring, proving that differentiation in vitro during cell culture did not prevent reprogramming to a totipotent state when the nucleus of these cells was transferred into an enucleated oocyte. In short, differentiated cells growing in culture could be successfully utilized for reproductive cloning of mammals, a situation similar to that demonstrated by Jon Gurdon when using cells derived from frogs, over 30 years earlier.

From a historical point of view these initial experiments involving cells growing in culture predicted that reproductive cloning with cells derived from a living adult animal would soon follow; and in 1997, the scientific community, indeed the entire world was shocked by the announcement that a living mammal had been cloned (Wilmut *et al.*, 1997). The birth of a cloned sheep derived by employing nuclear transplantation and a single mammary epithelial cell obtained from an adult animal was reported. Being a female (ewe) and given the cell type utilized for cloning, she was named “Dolly” (Fig. 3). The birth of Dolly, as with many great scientific breakthroughs represented a serendipitous surprise. Keith Campbell and Ian Wilmut were using fetal cells (fibroblasts) growing in culture for nuclear transfer, with the primary objective being to genetically modify the cells prior to nuclear transfer so to produce transgenic sheep. In one series of experiments, adult cells derived from mammary epithelia were utilized as a control treatment and not expected to develop to term, but resulted in the birth of Dolly.

It is clear that the birth of Dolly was a complete surprise to everyone involved. The overwhelming response from the general public and the world as a whole was also surprising given the long history of cloning animals and having previously produced cloned sheep and cattle from cells growing in culture. The major difference of course was that Dolly was derived from a cell obtained from an adult animal and as such it revived all sorts of scary scenarios about the possibility of cloning humans. The idea of being able to clone human beings was now too close to reality, sending a shock-wave throughout society. This resulted in an avalanche of controversy and ethical debates all over the world, not to mention legal actions quickly being taken at all levels of government to

Fig. 3 (a) World's first cloned mammal, a sheep named Dolly derived from a mammary epithelial cell collected from an adult animal. ban human reproductive cloning. Even now, legislation to regulate the application of reproductive cloning is in place and enforced throughout the world, with some countries even banning reproductive cloning of animals. The birth of Dolly resulted in an immediate and enormous increase in research conducted all over the world, focused on the utilization of reproductive cloning to produce genetically identical animals. Dozens of laboratory groups launched efforts to adapt methods involving nuclear transplantation in attempts to clone a wide variety of different animal species. Cloned animals representing more than 20 different species have now been produced by reproductive cloning, providing strong evidence for the robustness of nuclear transplantation as a tool for producing genetically identical animals.

Current State of the Art

Most reproductive cloning conducted today is focused on applications to livestock species and companion animals. Advancements in the technology have made it possible to produce cloned animals using almost any cell type that can be collected from an adult animal, however, the most common is fibroblasts derived by employing standard methods for tissue culture to a skin biopsy. Also, as indicated above, the goal in the vast majority of cases is not to produce large numbers of genetically identical animals, rather to obtain just a few, even one, of a very unique animal with a highly valued genotype. Examples of this include cloning prize winning steer to obtain a bull(s) that can then be used for breeding, cloning deceased pets, and even cloning animals that are deceased but which had cells cryopreserved for storage years prior to the time cloning was even thought possible (Westhusin *et al.*, 2007). In at least one case, cloned mice have been reported that were derived from cells obtained from whole carcasses that were stored in a normal freezer (Wakayama *et al.*, 2008).

The efficiency of cloning animals by nuclear transplantation remains low, with on average only 5%–10% of the cloned embryos transferred into surrogate mothers resulting in live offspring. The outcome also remains variable and uncertain. However, over time small changes have been introduced into the protocols to control cell cycle or changes in chromatin structure of the donor cells that have, at minimum, reduced the variability of outcomes and decreased the incidence of abnormal development including large birth weights. Early on there were concerns that cloned animals would age more quickly due to shortening of telomeres as a result of using cells derived from adult animals (and older animals) for nuclear transplantation. Experiments in our own laboratory and others demonstrated this not to be the case. CC, the world's first cloned cat is now almost 16 years old (Fig. 4), and the world's first cloned white-tailed deer (also derived from work in our laboratory) is 15 years old, well beyond the average age these animal species normally live.

Although 5%–10% of cloned embryos will develop into normal offspring, it is important to point out that the efficiency of nuclear transplantation is oftentimes misunderstood and seemingly much more robust than it truly is. The process involves several steps and losses occur at each of these steps. For example, one may need to begin with 1000 oocytes to obtain 500 that are usable. Enucleation may leave only 200 which survive the procedure to serve as recipients for donor cells, 100 may survive transfer of the donor cell into the enucleated oocyte, and only 10 develop into a normal cloned embryo. Following the transfer of these 10 cloned

Fig. 4 The world's first cloned cat, CC. (a) Cat from which donor cells were collected. (b) CC and her surrogate mother. Note that the cell donor is a calico but CC does not exhibit this coat color pattern, indicative that cloned animals do not always exhibit the same phenotype as the cell donor. It is also noteworthy that failure of the orange allele to express may indicate the inactive X chromosome was not completely reprogrammed by nuclear transplantation. Taken from Shin, T., Kraemer, D., Pryor, J., *et al.*, 2002. A cat cloned by nuclear transplantation. *Nature* 415, 859.

embryos one could expect to get on average only 1 cloned offspring. Again, this is extremely variable, but the example is not unusual and explains the considerable amount of time, effort and expense that is still required to produce animals by reproductive cloning.

This example also exposes the enormous challenges that can arise when attempting to apply reproductive cloning to certain animals. In dogs for example, surgical procedures must be employed to obtain viable oocytes from the oviducts following natural ovulation. Dogs do not respond to hormone treatments that are used in other species for superovulation and estrus synchronization, and they only exhibit estrus every 6 months – 1 year. As a result, considerable time and effort is required simply to produce a few cloned embryos which have to be surgically implanted into the surrogate female. Other species present even greater challenges, most of which have nothing to do with the process of nuclear transplantation itself, but the logistics of all the other steps required for “reproductive cloning”. In recent years, a few scientists have suggested the possibility of cloning long extinct species. Simple logistics and common sense make this highly unlikely. Where would one obtain oocytes to produce cloned embryos? What would serve as the surrogate mother? How would embryos ever be transferred, where and when? It is not unreasonable to expect reproductive cloning could potentially be used to re-derive some animal species that have become extinct, but the list would likely be pretty short.

At present, the overall inefficiency of reproductive cloning keeps the costs high, so the technology remains primarily a tool for the reproduction of elite commercial genotypes, i.e., animals with a specific/special purpose. Market demand has been estimated at approximately 100 horses per year, <500 cattle, and a few hundred pets (dogs and cats, **Fig. 4**). There is also a smaller but real demand for cloning in pigs, sheep and goats. The cost of cloning varies but ranges from 10 s of thousands of dollars to over \$100,000 depending on the animal and specific circumstances. Besides the application of cloning to reproduce specific genotypes, it is also important to point out that reproductive cloning continues to play a significant role in the production of genetically modified (GM) animals, in particular livestock (**Wheeler, 2007**). In fact, a common method currently employed to produce GM livestock is to first produce cells growing in culture that have the desired genetic modification, then utilize these as donor cells for nuclear transplantation (reproductive cloning).

Today there are literally hundreds if not thousands of scientific publications reporting various success rates with cloning animals by nuclear transplantation. Regardless of how the data are analysed and interpreted, reproductive cloning in animals remains a very inefficient process. Although numerous experiments have been carried out to identify a variety of different culprits potentially responsible for the inefficiency of cloning, such as abnormal epigenetic regulation of gene expression or problems with cell cycle synchrony; the true mystery that remains to be explained is how it works at all. It is unremarkable that embryos produced by nuclear transplantation fail to develop. The true “miracle” is that it actually sometimes works, ultimately resulting in a normal animal.

Glossary

Artificial insemination Manual deposition of semen into the female's reproductive tract.

Cryopreservation Method for ultralow temperature storage of sperm, oocytes and embryos.

Electroejaculation Application of electrical stimuli by a rectal or penile probe to induce semen recovery.

Embryo transfer Manual placement of pre-implantation embryos into the female's reproductive tract.

Fecal hormone metabolite analysis Endocrine method used to assess reproductive hormone byproducts in voided fecal samples.

In vitro fertilization Insemination of recovered oocytes to produce embryos in culture.

Laparoscopy Examination of the contents of the abdominal cavity using a fiberoptic telescope.

Introduction

The Earth is currently experiencing the sixth major extinction crisis in its four and one half billion year history, with population declines documented across most major wildlife taxa over the past 50 years. Of the ~5500 mammal and ~10,000 bird species in the world, 20% and 12%, respectively, have been classified under some degree of extinction threat. Causes for this ongoing extinction crisis are multiple and complex, but one overriding factor has been the exponential growth in human populations and related acceleration in resource consumption, predominantly habitat loss. Reversal of wildlife species decline will require concerted efforts addressing global socioeconomic issues and disparities coupled with immediate implementation of remedial actions to slow species loss. For many species, assurance populations may be needed to bridge this critical time period and ensure that these endangered taxa survive long enough to once again have the opportunity to thrive in nature.

Accredited zoological parks are working collaboratively on a regional, and, increasingly, global level to maintain and manage genetically and demographically viable wildlife populations under human care. The evolution of zoos and aquariums from menageries to conservation organizations is ongoing and essential if many of these species are to remain extant for the next century. The 231 institutions accredited by the US-based Association of Zoos and Aquariums (AZA) currently manage 217 mammal and 181 bird species, respectively, within Species Survival Plans (SSPs). SSPs use pedigree analyses to estimate the genetic relatedness of individuals in the managed population and make breeding recommendations to maximize genetic diversity (based on mean kinship values). Despite intensive management efforts, few of these populations (<10%) in AZA-accredited zoos are considered sustainable (>90% gene diversity) over the next 100 years – the genetic benchmark targeted by zoos. In the 356 facilities accredited by the European Association of Zoos & Aquariums (EAZA), similar breeding management programs (termed European Endangered species Programs, or EEPs) oversee 146 mammal species and 49 bird species with a comparable lack of genetic sustainability for most taxa projected over time.

The crux of the issue for most species is the availability of too few exhibit spaces within zoos for populations established initially with too few genetic founders, confounded by poor breeding success, leading to inbreeding and further decreases in genetic heterozygosity. The reversal of species decline within zoos, as in nature, requires concerted efforts globally, but, at least in zoos, this goal may prove attainable for some taxa with the judicious application of reproductive sciences. In particular, management challenges related to low breeding success, limited exhibit space, small founder number, and restricted gene flow may be addressed via reproductive science and technology.

Reproductive sciences encompass multiple disciplines including gamete biology, endocrinology, cryobiology and ultrasonography, which, in turn, are the fields most essential to wildlife propagation. These scientific disciplines fostered the reproductive technologies that generate the most media interest (whether for actual births or speculation about future offspring) but also have the greatest potential to produce meaningful and long-lasting benefits for species management and conservation. For wildlife species, the most relevant of these reproductive technologies comprise semen collection, hormonal and ultrasonographic analyses, artificial insemination (AI), in vitro fertilization (IVF), embryo transfer (ET), and semen/embryo cryopreservation. These technologies are considered almost rudimentary to many reproductive biologists studying laboratory rodents or agricultural species, in which high pregnancy percentages have been routinely achieved with frozen semen AI or frozen embryo transfer for decades. For most wildlife species, information of basic reproductive biology is extremely limited or non-existent and application of any assisted reproductive technology is unlikely to succeed until that deficit is addressed. The keys for effective wildlife propagation are to first establish that fundamental knowledge base and then build from that foundation to explore the appropriateness, feasibility and application of assisted reproduction for species management.

Understanding Basic Reproductive Physiology

Semen Collection and Analysis

Evaluation of semen production and quality is an essential component for basic characterization of reproductive traits in wild mammals and birds. For these analyses, effective and safe methods for semen collection must be available and suitable for use across diverse taxa. For some mammal species (e.g., elephants, gorillas, chimpanzees, cetaceans), voluntary collection using prostatic massage, artificial vaginas, or direct masturbation of non-sedated individuals has proven feasible (O'Brien and Robeck, 2010). However, these approaches can require time-intensive operant conditioning and training, limiting their usefulness on a population level. For most wild, intractable mammals, males must be anesthetized for semen collection, requiring proven drug regimens that provide adequate anesthetic depth while minimizing patient risk. The most common collection approach for mammal species involves electroejaculation, using a rectal or penile probe coupled with a controlled voltage electrostimulator to promote ejaculation of semen from anesthetized or sedated individuals. This approach is most commonly used with felids, canids, primates, and ungulate species (Herrick *et al.*, 2010; Pukazhenthi, 2016). For some mammal species, such as felids and bears, an alternative approach using urethral catheterization in combination with alpha 2 agonist drugs permits recovery of highly concentrated semen. High quality sperm samples also may be recovered from many mammals post-mortem by flushing the vas deferens and caudal epididymides (up to 24 h after death if tissues are kept chilled). For bird species, although semen collection has been attempted by electroejaculation, the preferred method is massage of the vent to directly express semen, or manual stimulation of the male to induce voluntary eversion of the cloaca and ejaculation (Malecki *et al.*, 2008). This technique has been effective in multiple avian species, from several raptor and pheasant species to birds of paradise. In some cases, imprinted birds have been trained to ejaculate onto inanimate objects such as a dummy bird model (houbara bustard), a hat (raptor species) or even a shoe (African penguin, California condor). Training and conditioning of birds for handling and semen collection is necessary for some species such as cranes and raptors, but less essential for other species, such as ducks and songbirds (Gee *et al.*, 2004).

Semen analysis methods are similar across mammal and bird species, comprised of assessment of seminal volume, sperm concentration, progressive motility (percentage of motile and rate of forward progression), morphology, and other characteristics, including acrosome and plasma membrane status (Herrick *et al.*, 2010; Gee *et al.*, 2004; Pukazhenthi, 2016). Although many of these traits may be evaluated subjectively, objective assessment methods using flow cytometry, videography and computer-assisted analyses for motility and morphology are becoming more routine with wildlife species. More advanced analyses including measurement of sperm metabolism, chromatin fragmentation, and sperm functionality (acrosome reactivity, heterologous *in vitro* fertilization) have been used with some felid and hoof stock species. For species such as primates, macropods and armadillos, semen recovery and analyses is confounded by presence of coagulum that may require thermal and/or enzyme-induced liquification. Seminal analyses in highly seasonal mammal and bird species may reveal poor sperm quality parameters initially, but these can rapidly improve as the season progresses. Seminal quality also may be partially dependent on the mating system, with higher motile sperm numbers and normal morphology observed in large herd species, and greater sperm numbers and larger midpieces in primates with polygamous mating systems.

Semen analyses provide basal information on the reproductive status of the individual male, including potential fertility, and normative values for the species as a whole (*ex situ*). Comparative seminal data from wild (*in situ*) populations are lacking for most mammals, with the exception of some felids (Florida panther, cheetah, lion, jaguar, Pallas' cat, black-footed cat), ungulates (giraffe, gerenuk) and African elephants (Hildebrandt *et al.*, 2012). As zoos increasingly collect and bank semen *in situ* from wild males as a potential source of new founders, more comparative data are expected to be generated for wild populations.

Reproductive Endocrinology

Endocrinology represents a vital scientific discipline for defining normative reproductive characteristics and basic hormonal patterns in wildlife species. The development of radioimmunoassays (RIAs) and, subsequently, enzyme immunoassays (EIAs) with broad cross-species applicability has allowed assessment of reproductive hormonal patterns in more than 100 wild mammal and bird species over the past 30 years (Brown *et al.*, 1994; Kersey and Dehnhard, 2014; Stoops *et al.*, 2016). Coupled with the ability to measure hormonal metabolites in excretory products (saliva, urine, feces) collected non-invasively, these immunoassays have provided our first detailed insights into the basal endocrine function that forms the basis for successful wildlife propagation. As steroid molecules are highly conserved and metabolism is similar across species, the same assays, using a limited number of group-specific antibodies, have been validated and applied across evolutionary-diverse taxa. The increasing importance of this wildlife-focused field over the past few years is reflected in the founding of a dedicated scientific organization, the International Society of Wildlife Endocrinologists (see Relevant Website section).

For many mammalian species, studies of basic reproductive biology include hormonal assessment of ovarian cyclicity, ovulatory mechanisms, seasonality, and pregnancy and pseudopregnancy. In birds, reproductive behavior and courtship studies have been more prevalent. Frequently, adrenocortical hormones also are measured to evaluate the effect of putative management stressors (exhibit size and complexity, noise, crowding, etc.) on reproductive function. These reproductive characteristics are primarily assessed by monitoring steroid metabolites (testosterone, estrogen, progesterone) in urine or fecal samples collected longitudinally from the individual/species of interest. Evaluation of feces and urine offers the added advantage that measured values represent the pooling of hormonal levels over several hours to days, with less fluctuation than observed with blood. For each species, the respective assays must be first validated by assessing hormone recovery during sample extraction, parallelism of serially diluted

samples with a standard curve, and relationship of assay results to physiological events, such as observed breeding, pregnancy and parturition. Depending on species, certain hormones/metabolites may not be adequately detected with standard assays. For example, fecal estrogens are readily measured in felids, but the commonly-used estrogen assays work poorly in otters, bears, and most rhino species. These variations likely occur due to differences in hormone metabolism prior to excretion, alternative excretory pathways (feces vs. urine) and poor cross-reactivity to the assay antibody. In many species, the main hormone metabolites are unknown, but can be determined using liquid or gas chromatography/mass spectrometry methods if identification of a more specific antibody/assay is required (Kersey and Dehnhard, 2014).

The reproductive profiles deduced from hormone monitoring provide valuable metrics for defining optimal endocrine characteristics for success reproduction and managing breeding pairs (e.g., determining time or season for pairing), but also assessing potential causes of infertility or sub-fertility in individual animals that fail to reproduce (Fig. 1). Similarly, normative profiles of estrus, non-pregnant luteal phases and pregnancy provide a benchmark for evaluating the effectiveness of ovarian synchronization/stimulation protocols for inducing appropriate hormonal responses, and determining pregnancy following natural breeding, AI or ET. For pregnancy diagnosis, longitudinal monitoring of fecal or urinary progesterone can detect temporal changes most consistent with either a non-pregnant luteal phase, pseudopregnancy or an ongoing pregnancy (Fig. 2). For some

Fig. 1 Fecal estrogen and progestagen metabolite profile in a black-footed cat, showing multiple non-pregnant luteal phases following spontaneous ovulation and an induced luteal phase in response to eCG/hCG treatment. Fig. 2 Urinary estrogen and progesterone metabolite profiles in four Indian rhino pregnancies produced via transcervical AI with frozen semen during natural estrous cycles. Reprinted from Stoops M.A., Campbell M.K., DeChant C.J., *et al.*, 2016. Enhancing captive Indian rhinoceros genetics via artificial insemination of cryopreserved sperm. *Anim. Reprod. Sci.* 172, 60–75, with permission of Elsevier Science.

species, other fecal or urinary pregnancy biomarkers (e.g., PGFM, relaxin, chorionic gonadotropins) may provide more definitive diagnoses (Kersey and Dehnhard, 2014). In tractable or easily restrained species, transabdominal or rectal ultrasonography can provide invaluable correlative data for hormonal assays, and allow real-time monitoring of ovarian function and pregnancy (O'Brien and Robeck, 2010; Stoops *et al.*, 2016).

Assisted Reproduction

Artificial Insemination

Artificial insemination (AI) represents the most direct approach to propagating wildlife – essentially simulating natural breeding without requiring the direct participation of the male (Pukazhenthil and Wildt, 2004). For some wildlife species, AI can be conducted vaginally or transcervically in a non-sedated, naturally-estrous female with minimal restraint, but for numerous other species, the AI process is much more complex. For many species, the availability of a domesticated reproductive model has been instrumental in making progress, most notably with domestic cats/wild felids, domestic hoof stock/wild ungulates and domestic poultry/wild birds. From an applied perspective, AIs (combined with semen cryopreservation) are conducted in zoos for four primary reasons, specifically to: (1) propagate behaviorally or physically incompatible pairs, (2) create genetic exchange between individuals housed in distant zoos, (3) introduce new founders from the wild into captive populations, and (4) allow long-term maintenance of genetic diversity within liquid nitrogen tanks (Pukazhenthil and Wildt, 2004; Swanson, 2006; Howard and Wildt, 2009). Prior to initiating AI studies, it is important to address its relevance for species management, and determine if AI is really the most appropriate strategy. Despite its relative simplicity compared to newer reproductive technologies, AI has been only moderately successful for propagating wildlife species in zoos, especially if the ultimate goal is production of viable, genetically-valuable offspring for population management. Of the world's >5000 wild mammal species, a total of 58 species (~1%) have been propagated with AI, with 34 of these species reproduced using frozen semen, the gold standard for management purposes (Table 1). Of the ~10,000 bird species, AI has proven successful in producing offspring in ~37 species, with 12 of these from frozen semen AI (Table 2). Relatively few laboratories globally are dedicated to studying the reproduction of wildlife species, which hampers progress in developing effective AI approaches and reflects the sparse availability of funding for these conservation-based research activities.

Considerations for successful AI in wild mammals and birds include (1) estrus detection and ovarian synchronization, (2) timing of AI, and (3) AI technique. For many species, the preference is to conduct AI during a natural estrus period, either by monitoring endogenous ovarian cyclicity over time or by employing pharmaceutical methods to induce estrus within a defined (fixed) time period. The benefit to conducting AI on a natural estrus cycle is potentially higher pregnancy percentages, but longitudinal monitoring of individuals for real-time detection of natural estrus can be challenging and costly, limiting its applicability to a few high profile species. Two of these species, the giant panda and black-footed ferret, are highly seasonal breeders, allowing intensive estrus monitoring to be restricted to a short time period in the spring months. By assessing vaginal cytology (ferrets) or urinary hormones (pandas) daily, the onset of natural estrus can be detected and AI timed coincidentally with spontaneous or induced ovulation, resulting in high fertility (Pukazhenthil and Wildt, 2004; Howard and Wildt, 2009). Similarly, AIs in elephants are conducted exclusively during natural estrus cycles, based on frequent blood sampling and monitoring of serum LH concentrations. Because elephants exhibit biphasic peaks in LH at three week intervals prior to ovulation, the detection of the first LH peak provides adequate lead time for AI scheduling (Hildebrandt *et al.*, 2012). Within zoos, these three species represent the prime examples of AI being used as a population management tool, with more than 25 offspring produced in each by AI (Table 1). AI procedures in cetaceans and rhinos depend primarily on using rectal/transabdominal ultrasonography and urinary hormone assays to monitor ovarian function and detect natural estrus phases for AI, also resulting in multiple pregnancies and offspring with positive population genetic impact (O'Brien and Robeck, 2010; Stoops *et al.*, 2016). In other species, primarily ungulates, ovarian activity is synchronized by inducing luteal regression (using prostaglandin injections) and/or ovarian suppression (using synthetic progestin implants or intravaginal devices) with females typically coming into natural estrus within a set time frame post-treatment for AI (Morrow *et al.*, 2009; Pukazhenthil, 2016). In contrast, felids are usually treated with exogenous gonadotropins (eCG or pFSH; hCG or pLH) to induce ovarian follicular growth and ovulation, but, in most cat species, response is confounded by endogenous ovarian activity and occasional spontaneous ovulations. Greatest AI success has been reported in the cheetah, with ~15 pregnancies reported following eCG/hCG treatment, presumably aided by intrinsically low levels of basal ovarian cyclicity (Howard and Wildt, 2009). Recent advances with felids include the use of oral progestin to suppress ovarian activity prior to exogenous gonadotropins (eCG/pLH) and fixed-time AI. In birds, AI usually is conducted during the species breeding season, which often is preceded by observation of specific reproductive behaviors. These displays may involve stereotypic rituals including courtship dances and collection of nesting materials (Gee *et al.*, 2004).

The timing of AI relative to spontaneous or induced ovulation also varies among species, but, for most mammals, insemination is conducted just prior to ovulation so the spermatozoa arrive at the site of fertilization prior to the ovulated oocytes. In some species, such as felids, AI is typically conducted post-ovulation because of concerns that anesthesia (required for most felid AIs) may interfere with the ovulatory process. In more tractable species (e.g., cetaceans, elephants), AI can be conducted both prior and after the expected time of ovulation. In birds, hormonal treatment is not used to induce estrus or egg laying, but timing of AI is less critical, due to the presence of oviductal sperm storage glands that allow several eggs to be fertilized with a single AI. In species that lay multiple eggs, production of the first egg is the most obvious cue to initiate AI to fertilize subsequent ova. For species that lay only single eggs, AIs should be conducted at least once weekly.

The AI technique also is often species-specific, depending on anatomical constraints and tractability of the individual. For many larger ungulates, use of drop chute restraint systems with conditioned animals has allowed transcervical AI to become the standard insemination method, whereas with small ungulates (such as deer), females are anesthetized for laparoscopic intra-uterine AI (Morrow *et al.*, 2009). In tractable species, such as elephants, rhinos and cetaceans, transcervical AI may be performed with minimal restraint (sometimes with standing sedation), whereas in carnivores, anesthesia is almost always required, with possible consequences for fertility. Vaginal and transcervical AI have been minimally successful in felids, necessitating development of laparoscopic uterine, and most recently, oviductal AI methods for improved conception (Howard and Wildt, 2009; Swanson, 2012). However, in other carnivores such as giant pandas and some canids, anesthesia of naturally-estrous females for transcervical AI has generated high pregnancy percentages. In birds, only the left ovary and oviduct are functional and semen is typically deposited in the vagina, oviduct or magna using manual restraint. Smaller birds can be handled and restrained by one individual while a second person inseminates, but AI in larger species such as cranes usually requires three people. For crane, raptor and ratite species, prior operant conditioning and training is necessary for AI procedures (Gee *et al.*, 2004; Malecki *et al.*, 2008).

The number of motile spermatozoa needed for successful AI varies by species and is partly dependent on the total sperm numbers typically recovered from the males. For some larger species (elephants, rhinos, cetaceans), sperm recovery numbers in the billions, allowing the use of very high inseminate doses (100–500 million) for intrauterine AI (O'Brien and Robeck, 2010; Hildebrandt *et al.*, 2012; Stoops *et al.*, 2016). In smaller species, such as felids, total semen recovery may average just 10–20 million sperm per ejaculate, limiting its availability for even a single AI attempt. Deposition of semen directly into the oviduct or distal uterus can substantially reduce sperm requirements, and allow the use of semen compromised by cryopreservation or suboptimal

morphology/motility (Swanson, 2012). In birds, deep insemination close to the sperm storage tubules usually produces superior fertility. For crane species, AI with ≥ 16 million sperm two to three times each week is recommended, but in other species, a single AI can fertilize multiple eggs. AI with excess sperm numbers should be avoided in birds since polyspermia and early embryo death may occur.

For wildlife population management, AI has been applied mainly to address issues of behavioral or physical incompatibilities, using freshly collected or chilled semen from resident males or males housed at nearby institutions. Although valuable for managing some populations, the dependence on freshly collected semen negates one of the primary advantages of AI – the ability to incorporate cryopreserved semen into species management. As with other aspects of wildlife reproduction, protocols for processing and cryopreserving semen from wild mammals and birds must be investigated on a species by species basis, requiring multi-factorial evaluations of each step in the cryopreservation process (Pukazhenthi and Wildt, 2004). The effectiveness of cryopreservation methods are often judged based on assessment of post-thaw motility, viability and acrosome status over time, less frequently with in vitro function tests, and rarely with AI trials. Although >30 wild mammal species have been propagated using AI with frozen semen (Table 1), technique efficacy is relatively low for most, and frozen semen AI is not a significant contributor to population management of wild mammal species. In birds, ~12 wild species have been reproduced using frozen semen, but as with mammals, this approach is rarely used for management purposes.

Embryo Transfer

Another assisted reproductive technology, embryo transfer (ET), has received considerable interest for propagation of wild mammal species. ET adds another layer of complexity, requiring either flushing of in vivo-produced embryos (produced by natural breeding or AI) from the female or generation of embryos in vitro following recovery and insemination of viable oocytes. ET provides a more direct approach for managing and conserving the genetic potential of females and, with IVM/IVF, facilitate the genetic salvage of deceased females. For individuals or species that produce minimal or poor quality sperm, IVF/ET also may represent the only feasible avenue for assisted propagation. As with AI, many ET protocols for wildlife are derived from those developed initially in domestic cattle, sheep, and cats. To date, ET has been used to produce term offspring in at least 30 wild mammal species (Table 3).

^aBirth of full-term offspring.

Abbreviations: Embryo source— IV, in vivo; IVF, in vitro fertilization; IVM, in vitro maturation. Transfer method— i, interspecies; LO, laparoscopic oviductal;

LU, laparoscopic uterine; SO, surgical oviductal; SU, surgical uterine; TC, transcervical. Embryo status— F, fresh; FT, frozen-thawed.

The primary difficulty for many species is recovery of viable oocytes or embryos in a minimally-invasive manner. For some wild ungulates, transvaginal oocyte aspiration has been possible, but for other species (elephants, rhinos), oocyte collection is challenging, confounded by lack of established ovarian hyperstimulation and IVF methods. In cats, protocols for ovarian stimulation, laparoscopic oocyte collection and IVF have been applied to ~15 species, with transfer of IVF-derived embryos resulting in offspring in eight species (Pope *et al.*, 2006; Swanson, 2006). In primates and ungulates, transcervical flushing of embryos produced from natural mating has facilitated successful ET in the past, but this approach is being supplanted by IVF-based embryo production methods.

As with AI, ET success requires knowledge of the basal reproductive physiology of each target species, with protocols adapted to their unique physiology and anatomy. Ovarian synchronization may rely on natural estrus phases or induced cycles using similar strategies employed for AI. ET techniques also are similar to those used for AI, with transcervical transfers preferred in ungulates and some primates, and laparoscopic oviductal methods favored for felids. One advantage to oviductal ET is the ability to transfer early-stage embryos, reducing the detrimental impact of extended in vitro culture on embryo/fetal health (Swanson, 2012). For transfer of freshly-collected or produced embryos, synchronized females must be readily available to serve as recipients. Interspecies ET (to domestic cows or ewes) was evaluated as one potential solution in ungulates, with the birth of multiple offspring in decades past, but efficacy was poor and this approach is rarely used now. Embryo cryopreservation presents another possible option for the shortage of recipients, allowing long-term storage prior to ET. Wildlife embryo cryopreservation has received much less research attention than semen freezing, with just 14 wild mammal species propagated to date via transfer of frozen-thawed embryos (Table 3). ET with fresh or frozen embryos does not contribute meaningfully to genetic management programs for any wild mammal species.

Emerging Reproductive Technologies

New reproductive technologies continually emerge from research institutions working with laboratory rodents or agricultural species, and, in many instances, are investigated for potential applicability to wildlife propagation. Early examples include interspecies embryo transfer, embryo micromanipulation (e.g., splitting, ICM transfer), and intracytoplasmic sperm injection (ICSI), and more recently, somatic cell nuclear transfer (SCNT), induced pluripotent stem cells (iPSC) for gamete derivation, semen freeze-drying, and sperm (sex) sorting. Some of these new technologies are valuable as investigational tools with wildlife, providing comparative insights into species-specific physiology and reproductive mechanisms, and a few have proven useful in limited applications for producing offspring. For example, AI with sex-sorted sperm in dolphins allows preferential production of offspring of the desired gender for management purposes (O'Brien and Robeck, 2010). Similarly, in birds, sexing of eggs via genetic analysis of blood collected from the developing embryo permits gender selection prior to hatching. However, extrapolation of novel approaches to wildlife propagation frequently results in failure, primarily due to lack of basal reproductive knowledge and awareness of species differences. When viable offspring are produced, these births may receive extensive media attention, but often are one-time events due to poor technique efficacy, funding barriers and lack of a defined applied purpose (creating a science-conservation disconnect). The still limited applicability of AI and ET for wildlife breeding management, after decades of research, exemplifies the challenges associated with applying even relatively basic reproductive technologies to propagation of non-domesticated species.

Future Priorities

Reproductive technologies play an important role in captive breeding management of wild mammal and bird species, notably for generating basal knowledge of species biology and improving natural breeding. Its true potential, however, has not been realized. The sustainability of >90% of managed populations in zoos cannot be assured for the next century through natural breeding alone. AI and, to a lesser extent, ET, in concert with sperm and embryo cryopreservation, can help to change that trajectory, but only if adequate resources (animals, research staff, infrastructure, funding) are available to advance these techniques beyond proof of feasibility to achieve adequate efficacy for applied use. Animal managers and zoo veterinarians also must embrace the science and receive adequate training to apply these new tools for species propagation. Once that benchmark is reached, these technologies will be poised to substantially benefit wildlife management programs, provided that zoos and society remain committed to supporting the broader implementation of these applied reproductive sciences.

Captive Breeding Wildlife: Fish, Amphibians and Reptiles

Paul D'Ortona and Scott McRobert, Saint Joseph's University, Philadelphia, PA, United States

© 2018 Elsevier Inc. All rights reserved.

Glossary

Amplexus The mating position for frogs and toads in which the male grasps the female around the waist or under the arms, from behind.

Anadromous A system in which ocean-living fish migrate into fresh water to spawn.

Anurans Frogs and toads.

Carapace The upper portion of a turtle's shell.

Catadromous A system in which fish living in fresh water migrate down rivers to the ocean to spawn.

Cloaca The common cavity into which the intestinal, urinary, and reproductive canals open in birds, reptiles, amphibians, many fishes, and certain mammals.

External fertilization Situations in which sperm and egg come into contact outside the bodies of the male and female.

Female Choice A mating system in which females choose their mates.

Husbandry The care and breeding of animals.

Intromission The process of inserting a male sexual organ into a female sexual organ during copulation.

Metamorphosis The process of transformation from an immature form to an adult form in two or more distinct stages.

Model Species Organisms that are ideal for scientific studies.

Morphology The form and structure of an animal.

Oviparity Producing eggs that mature and hatch after being expelled from the body.

Ovoviviparity Producing eggs that are hatched within the body, so that the young are born alive but without placental attachment.

Parthenogenesis The production of offspring via asexual reproduction.

Pedomorphosis The retention of juvenile features in the adult animal.

Phenotype The appearance of an organism resulting from the interaction of genotype and the environment.

Plastron The lower portion of a turtle's shell.

Protandry Form of hermaphroditism in which a male transforms into a female.

Protogyny Form of hermaphroditism in which a female transforms into a male.

Sequential hermaphroditism A reproductive system in which animals change sex.

Spawning The release of gametes (sperm and egg) directly into the water by aquatic organisms.

Squamata The largest recent order of reptiles that include lizards and snakes.

Temperature-Dependent Sex Determination A situation in which the temperatures experienced during embryonic/larval development determine the sex of the offspring.

Ventral Region The underside of an animal.

Viviparity The process of giving birth to living young rather than eggs.

Introduction

Reproductive activity is common, obviously, to every biological species on the planet. We often think of Darwinian natural selection, as 'survival of the fittest,' but in truth, a better abbreviation of Darwin's work would be, 'survival, and reproduction, of the fittest.' Because, indeed, survival alone will not address evolutionary success. Organisms must also reproduce in order to pass their genes on to the next generation.

But while reproduction is an elementary component in the life history of every species, the job of getting organisms to reproduce in captivity can be quite challenging. And yet, from many different perspectives, this task is being met. Scientists, conservationists, and entrepreneurs all find themselves in situations where breeding animals in captivity is necessary. From a scientific perspective, one of the major requirements for animals known as "model species," (species that are ideal for use in scientific studies), is the ability to easily create scenarios in which these organisms will reproduce in the laboratory. A classic example being the often misnamed "fruit fly" *Drosophila melanogaster*, whose glorious history as a model organism for the study of genetics was promoted by the ease with which these animals will prodigiously reproduce under the artificial conditions of the laboratory.

In this article, we will address the idea of captive reproduction in groups of animals that are loosely referred to as wildlife: Fish, Amphibians and Reptiles. In truth, these groups are so large, and so disparate, that a single article would be scarcely sufficient to cover any one of them alone. So, we will provide a brief overview of the major categories within each group, and examine the challenges and successes of captive breeding, focusing on a few model species, as well as species that would be considered quite exotic within a scientific laboratory. This will, in no way, provide exhaustive coverage on breeding behavior in these groups, but will offer a general overview.

Fish

Determining the total number of species, of any group, is a very difficult task, but fish, indeed, represent a huge collection of organisms. Estimates suggest there are somewhere between 30,000 and 40,000 different species of fish. However, again, this is only a rough estimate, and new species of fish seem to be discovered every year. The vast numbers of fish occupy a number of subgroups, including the bony fishes (Osteichthyes), whose skeletons are composed primarily of bones (example: tuna), and the cartilaginous fishes (Chondrichthyes), whose skeletons are composed of cartilage (example: great white shark). In general, a basic definition of a fish would be a streamlined aquatic organism that utilizes gills to extract oxygen from water.

As fish are such a large, diverse group, there are many ways to separate these animals into different categories. One common scheme is to divide this group into freshwater fish, which live in streams, rivers, ponds, and lakes, and salt-water, or marine, fish, which live in the oceans, coral reefs, and estuaries. The multitudes of species in each of these groups are specifically adapted to the salinity conditions of the places they live. And while most fish fall into one of these two categories, some fish actually spend their lives in both types of aquatic ecosystems. Anadromous fish, like salmon, are born in fresh water (typically the head waters of a river), swim downstream and spend their lives in the ocean, then return to the river to reproduce. Catadromous fish, like the American eel, are born in salt water, then migrate to freshwater rivers where they spend their lives before returning to the ocean to spawn.

Another way to divide fish is to identify different species by their mode of reproduction. Some fish are egg-layers. Some are live-bearers. And, within both groups there are species who provide parental care to their offspring and species that don't. There are even species that demonstrate sequential hermaphroditism, in which sex change is possible, and comes in two forms: protandry, where males change into females (i.e., clownfish), and protogyny, where females change into males (i.e., parrotfish).

In terms of captive reproduction, every fish species requires its own set of conditions. It is critical to work with animals that can be maintained in optimal health in captivity before breeding can even be considered. One well-known example is the zebrafish (*Danio rerio*). This species has become important in scientific research, owing largely to the fact that its eggs and offspring are transparent, allowing researchers to visualize the developmental process and test the effects of mutations on cell division and differentiation. And since zebrafish are vertebrates, they are more closely related to humans than other model organisms (like *Drosophila*). About 70% of the zebrafish genome is similar to that of humans, and this species has become a model system to understand the effects of human diseases like muscular dystrophy and many forms of cancer.

With respect to breeding, zebrafish are egg-layers, and their reproductive biology can easily be adapted to the laboratory (see [Westerfield \(2007\)](#)). Males and females are sexually dimorphic, with males being more streamlined and colorful, while females are plump and less colorful. Spawning is stimulated by light cues at daybreak and a common method for breeding includes housing a single male and female overnight in a small tank with a divider down the middle. At daybreak the divider is removed, allowing the fish to be together. Spawning involves the male and female simply releasing their gametes (sperm and eggs) into the water. Fertilization occurs outside the body and the eggs sink to the bottom. After spawning, the researchers can simply collect the hundreds of eggs produced in each spawning event.

An example of an egg-laying fish that is popular in both scientific laboratories and the pet trade is the convict cichlid (*Amatitlania nigrofasciata*), native to Central America. Their common name derives from the dark stripes that run along their bodies, which are reminiscent of uniforms worn by convicts in many prison systems.

Breeding convict cichlids requires little more than housing a small group of them in a large freshwater tank, preferably with lots of complex features (rocks, driftwood, plants, etc.). These fish are relatively aggressive, so care must be taken not to crowd them, nor to house them with smaller fish (which will get eaten), or with other aggressive species (such as other cichlids), as fights will occur. The mating system is female-choice, and the process will begin when a female picks a male and they pair off together in the tank (see [Noonan \(1983\)](#), [Leese \(2012\)](#), [Cleveland-Roberts and Itzkowitz \(2009\)](#)). However, if the owner wishes to exercise more control on this process by setting up specific male/female pairs, the sexes are relatively easy to identify, with females being more colorful, with darker stripes and bright orange, yellow and red pigmentation on their vents.

Breeding in *A. nigrofasciata* begins with the female choosing and preparing a site on which to adhere her sticky eggs. This will always be a hard surface. An ideal spawning location is a clay flower pot, laid on its side at the bottom of the tank. Flower pots not only provide a hard surface on which the female can lay her eggs, but also provides a shelter for the newly hatched young. Once the eggs have been laid, the male releases sperm into the water to fertilize them. This spawning system, like that seen in zebrafish, involves external fertilization.

Convict cichlids are highly involved parents, displaying brooding behavior. Both male and female parents guard their eggs and offspring, aggressively chasing other fish away from the spawning site. This can actually be quite stressful, and possibly dangerous, to other fish in a tank with a brooding pair of convict cichlids. They are, again, quite aggressive and almost any movement on the part of other fish may be interpreted as a threat to the young, eliciting an attack by the parents.

Amphibians

Reproductive behavior is one of the elements that helps define most amphibian species. These animals, which include Anura (frogs and toads), Urodela (salamanders), and Apoda (caecilians), typically begin life as aquatic larvae with gills, then undergo metamorphosis, transforming into a distinctly different adult form, which often live on land and respire through lungs. Amphibians are distinctly tied to freshwater (there are no salt water amphibians) as their eggs, typically laid in water, need to remain moist.

The fertilization of eggs is achieved in a number of ways by amphibians. For Anurans, fertilization is almost exclusively external. The male grasps the female around the waist or under the arms, from behind, and literally squeezes the eggs out of her, which he then covers with sperm. In the Urodela, fertilization is typically internal, but does not involve intromission. Instead, the male deposits a packet of sperm, which the female then picks up with her cloaca. And in the Apoda, fertilization is internal, and does involve intromission, with the male inserting his copulatory organ into the female's cloaca.

Frogs

Amphibians are well represented in both the pet trade and the laboratory, and thus captive breeding can be accomplished for a number of species. In the South American poison frog, *Epipedobates anthonyi*, males are territorial and court females by singing their high-pitched trill from their home bases. Singing is a common male courtship behavior amongst Anurans. The females, attracted by the song, enter a male's territory where he grasps them around their waist or neck, and holds the female until she releases around 15–40 eggs (in a clear gelatin), onto a leaf. The male fertilizes the eggs, and then guards them. Upon hatching, the male nestles into the egg mass and allows the tadpoles to wriggle onto his back. He then carries them to a small body of water and releases them. They will then complete their development and metamorphosis on their own.

Salamanders

Salamanders are characterized by four short limbs, rounded snouts, long/slender bodies, and the presence of a tail in both larval and adult stages. Most salamanders undergo metamorphosis, starting life as an aquatic form and becoming terrestrial as adults. However, some variation exists, such as in *Ambystoma mexicanum*, which exhibits pedomorphosis, and *Notophthalmus viridescens*, which experiences a life cycle that includes an aquatic larva, red eft (juvenile terrestrial stage), and fully aquatic adult, ultimately undergoing metamorphosis twice (Davis and Grayson, 2007). Salamanders also vary in their reproductive methods, exhibiting oviparity (Jockusch, 2004), with species that lay eggs in both aquatic and terrestrial environments, as well as ovoviviparity and viviparity (Velo-Antón *et al.*, 2012). Fertilization also varies, with most species exhibiting internal fertilization and some exhibiting external fertilization.

Among salamanders kept in captivity, fire salamanders (*Salamanca salamandra*), native to Europe, seem to be the easiest to breed in captivity. Mating takes place on land, with males depositing spermatophores for females to pick up, leading to internal fertilization. Depending on subspecies, fire salamanders can be either ovoviviparous or viviparous. Ovoviviparous subspecies will internally incubate eggs until giving birth to aquatic larvae, while viviparous subspecies will give birth to fully developed terrestrial juveniles. In addition to proper husbandry, captive breeding can be accomplished by housing a mature male and female together and by artificially creating seasonal changes in the enclosure. A gradual decrease in temperature down to mid-40°F should take place for about one month, and then gradually brought back to 67–75°F over a two-week period. Towards the end of the cooling period, an ovoviviparous female will deposit her offspring in water, and larvae can then be housed communally in a simple aquarium with a gentle filtration system and fed a diet of live blackworms, daphnia, and commercial salamander food. Once aquatic larvae develop all four legs, they should be moved to a shallow enclosure so they can easily exit the water.

Reptiles

Reptiles mark the next evolutionary step, when amphibians moved further from their reliance on freshwater for living conditions and reproduction. The reptilians have colonized just about every possible habitat, including the land, standing freshwater ponds, swamps and lakes, flowing freshwater rivers and streams, and even the open seas. Reptiles are represented by the lizards, crocodilians, snakes, and turtles, and are commonly found in captivity in the pet trade, laboratories, and zoos.

Lizards

Lizards belong to the order Squamata and consist of more than 6000 species. Diverse in their colors, patterns, and sizes, lizards like leopard geckos (*Eublepharis macularius*), crested geckos (*Correlophus ciliatus*), and bearded dragons (*Pogona vitticeps*) in particular, have become popular in the pet trade. Lizards have also become popular in research due to their unique qualities, behaviors, and relative ease of captive breeding. Examples of scientific research conducted on lizards includes temperature-dependent sex determination (Viets *et al.*, 1993) and embryonic development (Wise *et al.*, 2009) in *Eublepharis macularius*, toe pad adhesion in *Gekko gecko* (Autumn *et al.*, 2000), eggshell characteristics in *Correlophus ciliatus* (Andrews, 2017), and reproductive morphology and behavior in *Anolis carolinensis* (Lovern *et al.*, 2004).

Breeding lizards in captivity can be accomplished rather easily when species-specific needs are met. Crested geckos, native to New Caledonia, are an excellent example of a species that can be easily bred in captivity when maintained properly. Breeding crested geckos in captivity is as straightforward as introducing a healthy adult male into a healthy adult female's enclosure. Males usually become sexually mature around 9 months of age and females typically around 1-year old. Copulation usually occurs soon after introduction, with the male performing head bobs and chirping sounds, and then holding onto the female's neck with his mouth during copulation. Approximately 30–45 days later the female will lay 2 eggs in moist soil or moss (Hamper, 2005). Eggs should be removed from the enclosure as soon as possible and into an incubator (78–82°F) in damp vermiculite. Eggs typically hatch in 60–75 days.

Snakes

Snakes, also belonging to the order Squamata, consist of more than 3000 species, and are characterized by the lack of limbs and extra skull joints, allowing for a highly moveable jaw. Reproductive modes vary across species (Shine, 2003), with recent documentations of reproduction in snakes via oviparity (Brown and Shine, 2004), ovoviviparity (Birchard *et al.*, 1984), viviparity (Bertona and Chiaraviglio, 2003), and/or facultative parthenogenesis (Booth *et al.*, 2012). Similar to lizards, snakes have also become popular in the pet trade, with ball pythons (*Python regius*), cornsnakes (*Pantherophis guttatus*) and kingsnakes/milksnakes (*Lampropeltis* spp.) being very popular pets.

Captive reproduction in ball pythons starts with selecting sexually mature females weighing at least 1000 g, and males weighing at least 650 g. A cooling period (75–82°F) and feeding cessation for 2–3 months, followed by a return to normal temperatures (86–95°F), will stimulate copulation (De Vosjoli, 2003). Females will ovulate 6–30 days after copulation and will lay a clutch of 1–11 eggs. Eggs should be incubated (86–91°F) in damp vermiculite and will hatch in 53–60 days.

Turtles

Turtles are reptiles of the order Testudines (formerly Chelonia), best known for their bony protective shell consisting of an upper portion (the carapace), lower portion (plastron), and an interconnecting region (known as the bridge). Turtles are considered one of the oldest groups within the Reptilia, and today there are approximately 250 species. These animals have occupied almost every ecosystem on Earth, including freshwater rivers, lakes, ponds and swamps, brackish water estuaries and marshes, the ocean, and on land in forests, grasslands and deserts.

Turtles have long been part of the pet trade, although, in truth, turtles are difficult animals to keep in captivity. Turtles are very long-lived animals (lifespans of 60–80 years are not uncommon), and many people who purchase pet turtles simply grow tired of them. What's more, the lifestyle of most turtles requires both an aquatic zone for swimming and feeding, and a land area for basking. Such complex requirements are often hard to create in standard home fish tanks. However, despite concerns over longevity and aquarium care, turtles have been popular pets for decades.

Breeding turtles in captivity is not common for a number of reasons. Turtles often require many years (possibly 5–50) to reach sexual maturity. Owners must also have, obviously, a male and female of the same species for breeding to occur. And, finally, for successful breeding, the housing must include a location that will enable the female to dig a nest in which to lay her eggs.

Breeding in turtles is nearly the same for all species. Males approach females and typically perform some type of courtship display behavior. Females may initially retreat from males, who are persistent, following the females and continuing to preform courtship. If the courtship behavior is successful, the female will stop trying to escape the male, who will mount her from behind, allowing his tail to wrap around hers, such that his cloaca is lined up with hers. The cloaca is an orifice on the underside of the tail that serves as an opening for the digestive, urinary, and reproductive tracts. Typically, in turtles, female cloacae are located at the base of the tail, while male cloacae are located further down the tail, which enables males to press their cloaca up against the female's, allowing intromission to occur. Sperm is expelled from the male cloaca directly into the female, who is then able to store the sperm for fertilization of her eggs (see Pearse and Avise (2001)).

Probably the most well-known captive turtle is the red-eared slider (*Trachemys scripta elegans*). This animal, whose natural habitat is streams, ponds, and lakes in the southeastern United States, has been a mainstay of the pet trade and scientific research for decades. Unfortunately, as people all over the world have grown tired of their pets, this species has been released into the wild and is now found, as an invasive species, in practically every region of the world whose natural environment is capable of supporting turtles.

Reproductive behavior in *T. scripta elegans* begins with a fascinating male courtship display. When a sexually mature male encounters a sexually mature female he attempts to place himself in front of her, so he and the female are face-to-face. He will then extend both front feet and vibrate them rapidly. During this behavior, the males toe-nails (which are much longer than the female's, and are a good way to determine sex in these species), brush against the female's face. This behavior may cause the female to bite at the male's toe-nails, or simply flee. The persistent male will give chase, repeatedly trying to get in front of the female and vibrate his nails in her face. If he succeeds in stimulating the female sufficiently, she will stop trying to escape and simply pull her head into her shell. This allows the male to swim behind her, mount her, and use his cloaca to deliver sperm into her cloaca.

Following mating, in *T. scripta elegans*, or practically any other captive turtle, it is important to provide the female with a tank that includes an egg-laying region. At this point the male's work is done, and since he has no further role in reproduction, it is best to separate him from the female. The female will eventually begin searching for a location to lay her eggs. Female turtles are notoriously picky about the place they deposit their eggs, and so the keeper needs to create a suitable setting. For *T. scripta elegans*, a proper

nesting location typically consists of a plastic box containing a substrate such as soil and sand (although keepers may also try peat moss or hardwood mulch in place of the soil). The nesting substrate must be deep enough for the female to dig her nest. If the substrate is too shallow and she hits the bottom of the box before digging a deep nest, she will abandon the nesting attempt. What's more, the substrate needs to be kept moist, not wet. If these conditions are met, the female will dig a nest and deposit her eggs (typically 5–20 eggs for *T. scripta elegans*). She will then cover the nest very carefully and she is then done. Again, there is no paternal care in turtles.

Under captive conditions it is usually best for the keeper to now remove the eggs. Incubating the eggs in the female's tank may not be successful, and if it is, the keeper runs the risk of having the eggs hatch and the baby turtles entering the water with large adult turtles where they may drown or be eaten. So, removing the eggs is standard operating procedure. To do this, the keeper excavates the nest, taking care not to damage the fragile eggs. Once the eggs are uncovered they are often marked in pencil with a small 'x' to denote the upper region of the eggs. It is critical that the eggs are not rotated at this point, as rotation will kill the developing embryo. As each egg is marked and carefully exhumed, it can be placed into a suitable tray containing a suitable substrate, such as vermiculite or perlite. The tray of eggs can then be placed into an incubator. The temperature of the incubator is then an important consideration. In the turtles that have been studied, sex is determined by incubation temperature, with one range of temperatures causing the embryos to develop into females and another range of temperatures leading to male development (see Gilbert and Barresi (2016), Ewert and Nelson (1991)). In *T. scripta elegans*, lower temperatures (around 26°C) primarily produce males, while higher temperatures (around 31°C) primarily produce females.

Reproductive Technology (Non-Human/Non-Primate): Sex Control and Sterilization in Fish

Ten-Tsao Wong and Yonathan Zohar, University of Maryland, Baltimore, MD, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Fish, the most diversified group among vertebrates, exhibit prolific and variable reproductive strategies, which reveal the complexity of sex control in nature. Unlike mammals, no common mechanism of sexual development can be applied to all fishes. The gonads of vertebrates generally develop in the dorsal lateral lining of the peritoneal cavity and possess double origins, whereas the more laterally located cortical portion generates the ovary and the medullary portion gives rise to the testis. In teleost fish, only a single primordium (cortex) appears to be involved in the ontogeny of both ovary and testis. This may contribute to the greater plasticity of gonadal development in fish, in contrast with the more stable patterns found in higher vertebrates. This sexual plasticity offers a great opportunity for studying the evolution and mechanisms of sex determination and differentiation in nature, as well as practical applications of sex manipulation in fish.

Sex changes in hermaphroditic species and sexual dimorphisms in growth, size, appearance (ornamental fish) and maturation are vital to the practices of aquaculture broodstock management, seed production, and grow-out performance in commercial operations. In addition, gonadal development and sexual maturation compromise fish health, reduce production output and jeopardize the protection of wild stocks and ecosystems. As such, sex control and sterility induction are two key reproductive technologies that provide significant solutions to enhance environmentally-friendly and cost-effective aquaculture practices through (1) promoting controlled reproduction and constant and voluminous seed production; (2) offering monosex populations; (3) providing reproductively sterile populations to ensure genetic containment; and (4) preventing precocious maturation to enhance fish growth, health and market value.

Sex Control in Fish

The ability to manipulate sexual development in fish provides broad economic gains for aquaculture. Optimal sex ratio maximizes seed production in hatcheries. Hermaphroditic sex change creates instability of broodstock management of both sexes, which impairs the seed supply. The shortages of a specific sex in the protandrous gilthead seabream (Zohar *et al.*, 1995) or in the protogynous groupers (Tan and Tan, 1974), which change sex depending on their size and/or age, have been a major challenge in the development of seabream and grouper aquaculture. In some commercially valuable groupers, it may take 7 or 9 years to establish male populations (Chauvet, 1988; Tan and Tan, 1974). Sex control technologies also enable the monosex culture that helps achieve higher growth rates and reduces size variation and aggressive territorial or sexual behavior, as well as prevents undesirable precocious maturation and undesired reproduction in culture systems. All-female trout and all-male tilapia culture are two common practices in monosex culture to enhance economic return in the aquaculture industry (Devlin and Nagahama, 2002).

Hormonal Sex Control Approaches

Hormonal manipulation is the most common approach for sex control in fish. Desired sex is attained by exposing sexually undifferentiated individuals to female sex steroids (estrogens) or male sex steroids (androgens), with the aim of forcing the course of sex differentiation towards the favored sex. Identification of the responsive window, optimal dose, and duration of hormone treatment are principal steps towards the successful sex control of the undifferentiated gonad and the prevention of deformation and contradictory outcomes. The most widely used and effective masculinization hormone is 17 α -methyltestosterone (MT), which can be used to produce males directly or females indirectly (Fig. 1(A), also see genetic sex control approaches). In addition to the use of the more metabolically stable MT, aromatase inhibitors, such as Fadrozole, have been utilized to block the activity of aromatase, a key enzyme that catalyzes the formation of estrogen from androgen (Fig. 1(A)), which resulted in the reduction of estrogens and the acceleration of the female-to-male sex reversal process in grouper (Bhandari *et al.*, 2004). In contrast, the most commonly used feminization hormone is 17 β -estradiol (E₂), which can be utilized to produce females directly or males indirectly (Fig. 1(B), also see genetic sex control approaches). Although these approaches have been used in the industry, they are not widely accepted by regulatory agencies due to the potential of exposure of workers to the steroids or residues in the fish, water and/or culture systems (Rothbard *et al.*, 1990).

Temperature Sex Control Approaches

In teleosts, the process of sexual development, sex determination and differentiation, is controlled by genetic, environmental factors, and genotype–environment interactions during a critical phase of early development. Temperature is the most common environmental

Fig. 1 Hormonal sex control approaches. (A) Androgens or aromatase inhibitors are used for direct male production or indirect female production that involves genetic sex control approaches. (B) Estrogens are used for direct female production or indirect male production that involves genetic sex control strategies.

factor affecting sex determination. Since the first description of temperature-dependent sex determination (TSD) in Atlantic silverside, *Menidia menidia* (Conover and Kynard, 1981), about 60 different fish species have been reported to possess TSD, in which male-leaning sex ratios are linked to either high, low or extreme (both high and low) temperatures (Ospina-Alvarez and Piferrer, 2008). The actions of thermal cues require their interactions with genes that are involved in regulating sexual development, such as doublesex and mab-3 related transcription factor 1 (*dmrt1*), anti-Müllerian hormone (*amh*) and transcription factor SRY box 9 (*sox9*) related to male-development, as well as cytochrome P450 aromatase (*cyp19a1a*) and forkhead box protein L2 (*foxl2*) linked to female-development. Changes in expression levels of these candidate genes have been shown to be associated with temperature-induced sex differentiation, which triggers the thermosensitive and undifferentiated gonads to follow the testis- or ovary-developmental pathway. Furthermore, epigenetic-, cortisol- and hypoxia-mediated pathways have also been reported to mediate the effects of high temperature by inducing methylation of the *cyp19a1a* promoter, suppressing germ cell proliferation and *fshr* expression or increasing the testosterone/estradiol ratio, respectively, to promote male-skewed sex ratio (Shen and Wang, 2014).

Knowledge of TSD offers environmentally- and consumer-friendly approaches for sex control in fish. It can be utilized to control sex ratio in broodstock management by selectively breeding one sex over the other and producing sex-skewed or mono-sex populations in aquaculture applications. High temperature regimes (34–35°C) have been used to produce high male ratios (95% to 100%) of Nile tilapia (Desprez and Méléard, 1998) (Fig. 2).

Genetic Sex Control Approaches

One of most commonly used genetic sex control approaches to produce monosex populations for commercial aquaculture operations is the indirect utilization of hormone to first produce neo-males (XX) or neo-females (ZZ) that can be used to cross

Fig. 2 Signal pathways and molecular players involved in temperature-dependent sex determination.

Fig. 3 Gynogenesis or androgenesis to produce monosex populations.

with normal females (XX) or males (ZZ), respectively, to produce all-female (XX) or all-male (ZZ) populations (Fig. 1(A and B)). Other genetic approaches that have applied uniparental or parthenogenetic reproduction by gynogenesis or androgenesis to produce homozygous (double haploid) monosex populations have also been described. In these approaches, the genetic material of one gamete (either sperm or egg) is destroyed by UV or gamma irradiation, followed by fertilization with an untreated egg or sperm to form a haploid embryo. Later in development, a pressure, thermal or chemical shock is applied to inhibit either the second meiotic division (extrusion of the polar body) or the first cell division. When the first cell division is blocked, the resulting individual is a double haploid homozygous individual that inherits a duplicated set of chromosomes from the untreated gamete (Komen and Thorgaard, 2007), which can be also used to produce all-female (XX) or all-male populations (Fig. 3). In aquaculture practices, gynogenetic approaches have been successfully applied to produce all-female fish in several species including carp and flounders (Mei and Gui, 2015).

Another genetic sex control approach is to employ interspecies hybridization to produce all-male or all-female fish. In some closely related species, the strength of male- and female-determining genes located on autosomes or sex-chromosomes are different among different species, which may enable one species to override the others on sex determination to allow the

development of a skewed sex ratio or monosex population by interspecies hybridization. This approach has been successfully used to produce monosex populations in tilapia, bass and cyprinodons. For example, all-male tilapia populations were obtained by crossing female *O. mossambicus* (XX) with male *O. hornorum* (ZZ), and all-female bass can be achieved by crossing female striped bass with male yellow bass (Devlin and Nagahama, 2002; Mei and Gui, 2015).

In recent years, more sophisticated techniques including quantitative trait locus (QTL), single nucleotide polymorphism (SNP), random amplified polymorphic DNA (RAPD), simple sequence repeats (SSR), RNA-Seq and transcriptomic approaches were utilized to successfully identify and locate sex traits, sex- or sex-chromosome-specific markers, temperature-dependent sex reversal markers and sex-biased gene expression (Mei and Gui, 2015; Shen and Wang, 2014). These advances provide a strong foundation to accelerate the genetic improvement of sex control in commercial hatcheries through selective breeding programs. Ultimately, these efforts will assist in the production of monosex populations and maintenance of expected broodstock sex ratios in aquaculture operations.

Sterility Induction in Fish

Sterility carries environmental significance, as the escaped infertile fish are not able to propagate and/or interbreed with wild stocks. In addition, many farmed fish attain sexual maturity before reaching market size. Sexual maturation is associated with a substantial decrease in somatic growth due to the diversion of energy toward the development of the gonads. The period of intensive gonadal growth during sexual maturation also results in deterioration of flesh quality and an increase in susceptibility to stress and disease. Sterilization minimizes energy input toward gonadal growth while enhancing muscle (flesh) development and promoting fish health and overall performance (Manzoor Ali and Satyanarayana Rao, 1989; Zohar, 1989). Sterile fish are also a prominent tool for biological control of non-native fish. The sterile-male-release technique (Bergstedt *et al.*, 2003; Twohey *et al.*, 2003), similar to the sterile-insect-technique (Krafsur, 1998), can be used to control the populations of non-native species by competitively interrupting reproduction. Furthermore, sterility is a means for producers to protect their valuable, genetically selected strains from unauthorized propagation. Methods used to induce sterility are (1) manipulation of chromosome set number by triploidization or interspecies hybridization; (2) genetically-engineered germ cell ablation via expression of a specific transgene or knockout of an essential gene that disrupts germ cell development or causes germ cell death; (3) transient gene silencing to knockdown germ cell essential genes to disrupt germ cell development.

Chromosome Set Manipulation

The most common methods used to induce sterility in the aquaculture industry are chromosome manipulations to cause triploidization or interspecies hybridization, which disrupts the normal pairing of homologous chromosomes during gametogenesis and results in sterility. The triploidization method involves pressure or thermal shock of the fertilized eggs. To directly produce triploids (3N), shock is applied shortly after fertilization to inhibit the second meiotic division and retain the additional maternal 1N chromosome in the first polar body resulting in embryos possessing 2N from the eggs and 1N from the sperm. Indirectly, triploids can also be created from crossing tetraploids (4N) with diploids (2N) gametes. To produce tetraploids, shock is applied to block the first cell division (mitosis), resulting in individuals possessing 2N from the eggs and 2N from the sperm (Arai, 2001; Donaldson and Benfey, 1987). Hybridization is the crossing of genetically differentiated but closely related individuals or groups that are within a species (different line or strain crossing) or between separate species. This technique is used to produce fish with desired characteristics, which includes transferring other desirable traits from one line/species to another, combining valuable traits into a single group, or producing sterile individuals (Chevassus, 1983).

Chromosome set manipulation does not always result in 100% sterility of the treated fish. Studies done on triploid rainbow trout, Atlantic salmon and Atlantic cod found that male fish were seldom completely sterile and many of the treated Atlantic salmon females continued to possess a small number of oocytes that could be fertilized. Another disadvantage of chromosome set manipulation is that it requires that specific methods be developed for each species of fish being treated (Arai, 2001; Wong and Zohar, 2015b). Additionally, triploidy often results in compromised performances (Benfey, 1999; Maxime, 2008; Piferrer *et al.*, 2009), which prevents the implementation of this strategy in the industry.

Germ Cell Depletion Technology

The recently updated strategies that have been used to produce sterile fish are genetically-engineered germ cell depletion methods that disrupt germ cell development or cause germ cell death (Wong and Zohar, 2015b). Among these, one approach is to disrupt primordial germ cell (PGC) development. In fish, PGCs, the precursor cells of gametes, are specified outside of gonads during early development, and then migrate to the developing gonad, guided by a gradient of the chemokine, stromal-derived growth factor 1a (Sdf1a). Therefore, an inducible over-expression of Sdf1a was used to mask the Sdf1a gradient and to saturate the Sdf1a receptor, Cxcr4b, on PGCs, which prevented PGCs from responding to the endogenous Sdf1a signal and from migrating to the developing gonads. As a result, the treated fish developed into sterile individuals with severely under-developed gonads that lacked germ cells (Wong and Collodi, 2013). Another approach is to express *E. coli* nitroreductase specifically in the germ cells. When the fish were

treated with metronidazole, the nitroreductase catalyzed production of a cytotoxin that killed the germ cells. A third method is a maternal sterility approach that targets the elimination of PGCs, using a maternal deposit mRNA that encodes a pro-apoptotic protein B-cell lymphoma 2 associated X protein (Bax). Expression of pro-apoptotic Bax protein subsequently activates caspases and DNases, which leads to apoptosis and the elimination of PGCs. The latest approach is to knock out *deadend* (*dnd*), an essential gene for early germ cell development in fish. *Dnd* is an evolutionarily conserved RNA-binding protein that is specifically expressed in PGCs and plays a critical role in their development during embryogenesis (Weidinger *et al.*, 2003). In Atlantic salmon, homozygous *dnd* knockout effectively ablated the germ cells, which resulted in the production of sterile fish (Wargelius *et al.*, 2016). Results obtained from these transgenic strategies indicate that transgenic ablation of the germ cells to produce reproductively sterile fish is achievable. However, a major downside of these approaches is that it requires the generation of genetically-engineered fish in each species, thus introducing genetic modification into fish and leading to greater ecological risk, long delays for regulatory approval and potential consumer resistance.

Transient Gene Silencing to Disrupt Germ Cell Development

Due to negative public perception, genetically modified foodfish may face long-term resistance from consumers. To overcome the serious disadvantages and hurdles of previous sterilization methods, non-transgenic approaches to produce reproductively sterile fish are desperately needed to reduce food safety concerns and move aquaculture operations toward more environmentally responsible production. As such, a bath-immersion approach to efficiently deplete germ cells and produce sterile fish without introducing genetic modification into fish was developed. In fact, a transient gene-silencing method has been used in the laboratory to produce small-numbers of sterile fish in several species (Wong and Zohar, 2015b). This approach involved microinjecting embryos with a “gene silencing” Morpholino oligomer (MO) that transiently blocked *Dnd* protein expression (*dnd*-MO), which disrupted PGC development, and ultimately resulted in the production of reproductively sterile fish. This finding, together with the production of sterile fish by *dnd* knockout in Atlantic salmon (Wargelius *et al.*, 2016), indicates that blocking *Dnd* function may induce widespread reproductive sterility in fish. One important consideration, however, is that, *dnd*-MO is a relatively large molecule (7–8 kDa) that would not typically be able to cross the egg chorion, a thick acellular multi-

Fig. 4 Vivo conjugated Morpholino oligomer (MO) against *deadend* (*dnd*-MO-Vivo) induced sterility in fish.

layer envelope, and reach the embryos without using microinjection. To overcome this hurdle, a bath-immersion technology was developed to administer the *dnd*-MO into fish embryos using a molecular transporter, also known as Vivo, comprised of a dendrimeric oligoguanidine with a triazine core. Vivo can effectively carry *dnd*-MO across the chorion, enter the embryo and reach the target PGCs. Indeed, immersion of zebrafish embryos in the Vivo-conjugated MO against zebrafish *dnd* effectively disrupted PGC development (Fig. 4). The failure of normal PGC migration and development led to 100% production of reproductively sterile fish (Wong and Zohar, 2015a). Currently, this technology is being transferred from zebrafish, the experimental model, to rainbow trout, Atlantic salmon, tilapia and sablefish. Since the egg chorion differs between species, the immersion conditions will need to be optimized for each species. The successful development of this technology in multiple aquaculture species could have profound implications for eliminating reproductive threats, as well as enhancing fish health and performance. It thus alleviates public concerns associated with food safety and an adverse environmental impact of aquaculture.

Concluding Remarks

During the past two decades, the rapid progression of new biotechnologies, bioinformatics and molecular tools has prominently advanced our knowledge of the genes involved in regulating gonadal development, sex determination and differentiation, and the mechanisms by which environmental factors interact with these genes to alter the outcomes of sexual development. Therefore, novel biotechnologies that incorporate current and expanding knowledge will indeed lead to further successful advances in sex control and sterility induction of fish. The commercial implementation of these superior and reliable technologies will effectively promote more environmentally-friendly and cost-effective aquaculture production practices.

Glossary

Adenogenesis The development of a gland.

Anogenital Relating to the anus and genitals.

Blood-brain barrier (BBB) Protects the brain from most pathogens.

Castrati singers Male singers in the 18th century castrated in boyhood so as to retain a soprano or alto voice.

Endometrial adenogenesis Development of new blood vessels in the endometrium (the mucous membrane lining the uterus, which thickens during the menstrual cycle in preparation for possible implantation of an embryo).

Eunuch a man who has been castrated, especially (in the past) one employed to guard the women's living areas at an oriental court.

Fallopian Tubes Tubes through which an egg travels from the ovary to the uterus.

Human chorionic gonadotrophin A hormone secreted in the female reproductive tract upon conception, in order to aid implantation of the fertilized egg to the endometrial lining.

Hypothalamic hypogonadism A condition characterized by alterations or lack of sex steroid production by gonads due to a problem with the pituitary gland or the hypothalamus.

Hysteroscopy A procedure in which a device called a hysteroscope is inserted into the uterus through the cervix to view the inside of the uterus or perform surgery.

Laparoscopy A surgical procedure in which an instrument called a laparoscope is inserted into the pelvic cavity through a small incision. The laparoscope is used to view the pelvic organs. Other instruments can be used with it to perform surgery.

Microphallus A small penis.

Minilaparotomy A small abdominal incision used for a sterilization procedure in which the fallopian tubes are closed off.

Orthologs Genes in different species that have evolved from a common ancestral gene by speciation and that normally retain the same function in the course of evolution.

Perinatal Relating to the time, usually a number of weeks, immediately before and after birth.

RF-amide superfamily Characterized by the possession of an Arg-Phe-NH₂ motif at their C-terminal extremities.

Sterilization In fertility, to eliminate the ability of a person or animal to produce offspring, as by altering or removing the reproductive organs.

Tachykinins Family of peptides, which cause hypotension, smooth muscle contraction (e.g., contraction of gut and bladder), and secretion of saliva.

Zona pellucida A complex glycoprotein matrix surrounding the mammalian oocyte and early conceptus.

Sterilization

Definition and Context of Sterilization

In reproductive terms, sterilization is a term used to describe the elimination of the ability of animals, including humans, to reproduce by removing or altering the function of the reproductive organs. In the past this involved permanent solutions, such as irreversible surgical intervention, but increasingly, the trend is towards developing methods that are reversible should the need or desire to reproduce arise. Fertility control in humans, companion animals, farm animals, zoo animals and wild animals (including feral and pest species) have different criteria, requirements and hurdles that need to be overcome when it comes to development of effective sterilization methods ([Garside et al., 2014](#)). Some of these are considered below, but this is by no means a comprehensive list.

Surgical Sterilization Methods

Human: Female tubal ligation

In women, the surgical sterilization procedure is known as tubal occlusion. This involves closing the fallopian tubes to prevent the egg from moving to the uterus and prevents the sperm and egg from meeting. It is a highly effective method, and less than 1% of women become pregnant within 1 year of having the procedure. After 10 years, the pregnancy rate can rise to 4% depending on the

method used. The three main methods are minilaparotomy, laparoscopy or hysteroscopy. A tubal ligation reversal is a procedure to restore fertility after a woman has had tubal ligation, during which the blocked segments of the fallopian tubes are reconnected to the remainder of the fallopian tubes. Success rates depend on the initial extent of surgery and age of the patient; pregnancy success rates range between 45–69% and are lower in the first year after reversal (van Seeters *et al.*, 2017).

Human: Male vasectomy

Historically, human males have been castrated since ancient times, to provide eunuchs as guardians of harems in the Middle or Far East or to produce castrati singers. Surgical procedures involved severing the spermatic chords or crushing the testis with the fingers (Koutsiaris *et al.*, 2014). Today in men, the surgical sterilization procedure is known as vasectomy and is mainly used for contraceptive purposes. In a vasectomy, the vas deferens are tied, cut, clipped or blocked to prevent the release of sperm, which in turn prevents an egg from being fertilized. This procedure is slightly more effective than tubal ligation in women, after 1 year. Around 3–6% of men opt for surgical reversal due to changes in circumstances, indicating that there is a need for reversible sterilization methods (Patel and Smith, 2016).

Animal: Female ovariectomy

Tubal ligation and vasectomy are not commonly carried out in companion or farm animals. Instead, gonadectomy is performed. In females, this is known as spaying (or ovariectomy) where the uterus and ovaries are removed (DeTora and McCarthy, 2011). This is commonly carried out in cats and dogs, but is avoided in larger animals such as horses and cattle. Similarly, this is not a method applied to wild and pest animals for economical and logistical reasons.

Animal: Male neutering

In males, in a procedure known as neutering or castration, each testis with attached epididymis is removed. In dogs, both gonads are usually removed through a single incision made just anterior to the scrotum and the incision is sutured closed. Typically in cats, an incision is made into each side of the scrotum and left open to heal. This method is also used for small farm animals such as piglets. In larger farm animals, gonadectomy is performed, but does not utilize surgical procedures (also known as bloodless or closed techniques, see section below).

In males, the reason for castration varies from reducing aggressive behaviour, improving management in the presence of female animals, to prevent unwanted off-spring, to promote weight-gain in meat animals and to treat injury to the testes or to correct scrotal hernia.

Non-Surgical Sterilization Methods

Due to the expense, inconvenience of surgery and risk of infection, a range of non-surgical sterilization methods have been developed. In the following sections, we will consider some of the alternatives, some of which are in mainstream use, while others are likely to become mainstream in the future.

Closed methods of castration

A range of methods is available, mainly used for castrating male farm animals (see Relevant Websites section). The main advantage of these methods over surgical gonadectomy is there is no need for anaesthesia; however, some of these procedures are considered to be inhumane.

- 1 The Burdizzo® clamp involves crushing the spermatic cords in such a way as to prevent blood from reaching the testicles. Once the blood supply ceases, necrosis occurs and the testicles shrink and eventually deteriorate. The cords are clamped one at a time and at different levels in order to allow enough blood to the scrotal sac to prevent gangrene. This procedure is commonly used in farm animals such as goats, sheep and calves.
- 2 Elastic rubber rings are used in ram lambs, calves and kid goats, with certain age limitations. The rubber ring is placed around the scrotum, above the testicles.
- 3 The short scrotum method also involves a rubber ring, but this time placed below the testicles to push them closer to the body wall to place them at body temperature (to encourage infertility). The disadvantage of this method is that the sex hormones are still produced, so this does not prevent aggressive behaviour.

Synthetic steroids and non-steroidal compounds

There has been a drive to develop chemical methods to enable reversible sterilization. These are designed to have wider application for situations where controlled fertility is required. In humans, companion animals or zoo animals, steroids and non-steroidal implants or injections are commonly used.

Products used in humans

In humans there are a wide range of oral pills, injections, implants and vaginal rings containing steroid and non-steroidal compounds. Up to date and reliable information can be found on government health websites, such as the National Institutes of Health website. In brief, the NHS has established a comprehensive contraception guide that has recommended the utilization of

contraceptive injections (Medroxyprogesterone acetate, MPA: Depo-Provera[®]; Norethisterone: Noristerat[®]), combined pills (Monophasic: Microgynon[®], Brevinor[®] and Cilest[®]; Phasic: Binovum[®] and Logynon[®]; Every Day: Microgynon ED[®] and Logynon ED[®]), progesterone-only pill (Desogestrel: Cerazette[®] and Cerelle[®]; Norethisterone: Micronor[®] and Noriday[®]; levonorgestrel: Norgeston[®]), vaginal rings, intrauterine devices and systems, and contraceptive caps, implants, patches, and condoms. Reviewed by [Garside et al. \(2012\)](#).

Products used in animals

Typically, in companion animals, progestin contraceptives are used in various countries in the form of injections or oral contraceptives. Synthetic progestins and their brandnames, include megestrol acetate (MA or MGA; Megecat, Ovaban[®]), MPA (Depo-Provera[®]), and proligestone (Covinan[®]). Some of these are also used in zoo animals. Over population of some pest animals (e.g., deer) can also be treated using steroids used to regulate estrus in cattle and there are various symposia that describe these and other contraceptive developments on the United States Department of Agriculture (USDA) Animal and Plant Health Inspection Service (APHIS) website.

In male companion animals, a number of products have been developed, including Zeuterin[™] or EsterilSol[™] which is an intratesticular injection (which may no longer be on the market, but still has FDA approval), gonadotrophin releasing hormone (GnRH) agonists such as Suprelorin[™] which is a slow release subcutaneous implant of a GnRH analog (deslorelin) used in male dogs to suppress libido and fertility for 6 or 12 months and the progestin contraceptives used in various countries in the form of injections or oral contraceptives, typically used in female companion animals, but with some use in male animals as well.

Upto date information for companion animals can be found in the Alliance of Contraception in Cats and Dogs website (ACC&D) or for zoo animals information is available from the Saint Louis Zoo website. In some wild animals (e.g., cheetah and leopard), deslorelin (Suprelorin GnRH agonist implants) has been used to disrupt fertility. The AfriCat website also describes other species (monkey, wild dog, baboon, mandrill, tiger) for which this product works, but larger animals such as the elephant require immunocastration.

Some companies, such as Senes Tech, a US Biotechnology company are developing products that chemically delete oocytes in female rodents, using a chemical solution of 4-vinylcyclohexene diepoxide (VCD) in bait stations (see Relevant Websites section). The chemical is rapidly metabolized by the animals, and so does not affect the food chain. The company is also developing products for use in other pest species; taking into account sensitivity to the sterilant and the method of delivery.

Natural compounds: Potential antifertility activity

There are a vast number of natural compounds identified as having antifertility activity, which have been published by [Kumar et al. \(2012\)](#). Natural products usually require chemical synthesis in order to produce sufficient quantity of the active, or use with suitable delivery systems to ensure the compounds are efficiently administered. The original birth control pill originated from the compound diosgenin, isolated from Wild Yam (*Dioscorea villosa*) – this story exemplifies the timelines and challenges associated with natural product development ([Ferro and Garside, 2011](#)).

Immunocastration

In the case of wild animals and pests, logistics of trapping and administering long-term sterilization have driven many of methods described in this section, while others have been developed for contraceptive as well as anti-cancer approaches in humans and for animal welfare reasons in farm animals. Many of these have been developed for male animals. The first vaccines were developed in the 1970s and research in the field reached a height in the 1990s. The concept was that immunocastration would involve harnessing the immune system to target key components of the reproductive system (hormones and gametes). The main focus has been on gonadotrophin releasing hormone (GnRH), follicle stimulating hormone (FSH) and luteinising hormone (LH) in both males and females, as well as human chorionic gonadotrophin (hCG) in females. However recent fertility controlling hormones have been discovered, that has expanded potential targets to include kisspeptin (KP) ([Greives et al., 2008](#)). While the discovery of gonadotrophin inhibitory hormone (GnIH) has extended research into the role of both KP and GnIH in surgical castration and immunocastration in males, and differences thereof, indicating that this field is still in its infancy and we have much to learn ([Han et al., 2017](#)). In addition, immunocastration vaccines have been developed to disrupt sperm-egg interactions, by targeting key components of the gametes, with some success in female animals. [Fig. 1](#) shows some of the targets in the female system.

Established hormonal targets: GnRH, hCG, LH and FSH

Anti-GnRH vaccines have been in development for several decades, and there are different products used in male farm, wild and pest animals ([Garside et al., 2014](#)). Due to the complexity of GnRH control over female fertility, and the discovery of several isoforms of GnRH and receptors has restricted the development of these vaccines in humans (particularly women), whereas in other mammals vaccine development has advanced to products on the market. The most advanced anti-GnRH vaccine used for controlling fertility in wild animals is GonaCon[™]. This consists of a GnRH-hemocyanin conjugate, which was developed by the National Wildlife Research Center in the US (the research arm of the USDA APHIS) to induce antibodies against GnRH and to remove circulating GnRH from the body ([Benka and Levy, 2015](#)). The US Environmental Protection Agency (EPA) has also approved its use in female white-tailed deer, with GonaCon[™]-Equine being used in female wild horses and burros. This vaccine is also thought to be suitable for female felines.

Fig. 1 Vaccine targets in the female reproductive system.

Another hormone that has had a long history in immunocontraceptive development is hCG. Vaccination against hCG targets the egg at implantation, resulting in a localized vaccine that would only take effect in the event of conception, minimizing systemic side-effects. Problems with achieving suitable levels of neutralizing antibodies, and maintaining the vaccine response for a sufficient length of time limited the use of this vaccine as a contraceptive.

Some early studies in the 1980s were carried out on immunization against LH in female sheep. Later studies were carried out on immunization against the LH receptor, in cats and dogs, whereby corpus luteal activity was reversibly suppressed. However, these targets have not progressed to the market. On the other hand FSH immunization has been examined in humans, but only as a potential male immunocontraceptive.

Recent hormonal discoveries: KP and GnIH

In terms of KP, there is some evidence that the *KISS 1 gene* is being investigated in DNA immunocastration vaccine in ram lambs (Han *et al.*, 2015), but as yet information regarding this approach in female animals has not been published. KP is involved in various physiological pathways as described below, indicating that the complexity of the role of KP (not only in fertility) warrants that an immunocastration approach should proceed with caution. Understanding the role of these hormones will help identify future applications in immunocastration.

Role of KP and GnIH in regulation of the reproductive axis

As this is a relatively new field, the role of these hormones is described in some detail here. The HPG axis, which governs reproduction, is regulated by a complex network of stimulatory and inhibitory factors (Greives *et al.*, 2008). The dynamic and cyclic nature of the female reproductive function and the potency of stimulatory signals of the HPG axis, necessitates the existence of counterbalance inhibitory mechanisms, in order to keep stimulation at check and allow adaptation of reproductive maturation and function to different endogenous and environmental conditions. One of the main stimulatory factors in the initiation of the onset of puberty and control of adult fertility is KP (Yang and Dhillon, 2016). This peptide is encoded by the *KISS1 gene* and stimulates GnRH secretion from the hypothalamus via the KISS1 receptor (KISS1R, previously known as GPR54). In 2003 two independent research groups showed that loss of KP signaling causes hypothalamic hypogonadism (HH) in humans and mice (see review Lippincott *et al.*, 2013).

In 2000 a novel peptide of the RF-amide superfamily, named GnIH was identified in birds. Later, putative orthologs of GnIH named RFamide-related peptides (RFRPs) were identified in mammals including humans, with the capacity of inhibiting gonadotropin release. Of interest, it was shown that GnIH may not directly inhibit KP signaling in GnRH neurons (Leon and Tena-Sempere, 2016).

KP as a gatekeeper of the fertility

Numerous examples of genetic dysfunctions of KP signaling implicate the crucial role of this system in regulation of fertility (Sills and Walsh, 2008). In humans, inactivating GPR54 mutations cause normosmic HH, while activation of GPR54 signaling is associated with premature puberty. Moreover, patients with mutations that inactivate KP signaling are infertile. Similarly, mice with mutations in KP and the KP receptor, *Kiss1*(−/−) and *Kiss1r*(−/−), respectively have abnormal sexual maturation and infertility. Additionally males show defects in spermatogenesis with impaired production of spermatozoa, with these being more pronounced in *Kiss1r*(−/−) than in *Kiss1*(−/−) mice (Mei *et al.*, 2011). In a mouse model with deletion of the *Kiss1r* gene only in the GnRH neuron, it was found that male knockout animals had a microphallus and decreased anogenital distance compared with wild-type controls. Since both processes are androgen specific, it was suggested that disruption to the kisspeptin receptors on the GnRH neuron is specifically capable of altering the production of sex steroids. Moreover, delay in pubertal onset was observed both in male and female knockout mice, and circulating gonadotrophins were lower than in wild-type mice. Additionally, fertility was affected with no pregnancies observed when knockout males were mated with female mice previously shown capable of becoming pregnant. The above findings indicate a role for KP at the level of the GnRH neuron on pubertal onset and reproductive health (Novaira *et al.*, 2014). Furthermore, in genetically modified mice, peripheral KP signaling is indispensable for endometrial adenogenesis and function, essential aspects of reproductive competence.

KP does not act alone: Role of KNDy neurons

However, KP does not act alone and a mechanism underlying pulsatile GnRH release in rodents is believed to be the synchronized activity of a subset of arcuate nucleus (ARC) neurons in the part of the brain called the hypothalamus, termed KNDy neurons, expressing neuropeptides: KP, neurokinin B (NKB) and dynorphin (Dyn). It was proposed that pulse generation is initiated in the KNDy neuronal network by a reciprocating interplay of stimulatory NKB signals and inhibitory Dyn inputs. In rodents another population of KP neurons, in the anterior periventricular (AVPV) was found. While, the ARC neurons seem to be important for the initiation of the puberty process, normal pulsatile LH release and estrous cyclicity; the KP neurons in the AVPV control the LH surge in females. In males, KP neurons play a role in activation of neurons during the perinatal period, and that the subsequent GnRH surge generates testosterone necessary for ensuring sexual differentiation of the brain (Lehman *et al.*, 2010).

In humans, KP expression has also been found within the hypothalamus in the AVPV and the infundibular region (analog of the rodent's ARC). However, unlike in rodents and sheep, the homologous KP and NKB neurons rarely express Dyn – but often exhibit Substance P (SP) immunoreactivity, indicating remarkable species differences in the neurochemical phenotype of these neurons.

KP is a potent activator of the reproductive axis

Proper KP/GPR54 signaling is viewed as the principal trigger for activation of GnRH neurons and subsequent ovulation. Thus, elucidation of how this pathway is modulated is likely to bring novel pharmacologic strategies for fertility treatment and contraception. In animal models KP affect gonadotrophin release in females as well as males. KP induces the LH surge necessary for ovulation and oocyte maturation and in transgenic mice null for KP or its receptor, lack the LH surge and subsequent failure of ovulation is observed. KP administration has been found to induce ovulation in several mammals, including sheep, musk shrews and rats (Clarkson *et al.*, 2008; Caraty *et al.*, 2007; Matsui *et al.*, 2004).

In healthy human volunteers, the acute intravenous (icv) administration of KP increases plasma LH, FSH and testosterone (T) levels without side effects in both males and in females, particularly in the preovulatory phase of the menstrual cycle. Acute KP stimulates gonadotropin secretion in a wide range of species of non-human mammals, including rats, mice, hamsters, sheep, pigs, goats, cows, horses, and monkeys. Importantly, administration of KP by either the subcutaneous (sc) or icv route stimulates gonadotrophin release through influencing GnRH secretion responses in human subjects with reproduction disorders. Different lengths of KP are found, of 54, 14, 13 or 10 amino acids (aa), which share a common C-terminal 10 aa sequence. While both KP-54 and KP-10 have been widely used to stimulate the reproductive axis, it was found that KP-54 was able to cross the blood-brain barrier (BBB) and had a longer half-life in a bloodstream (d'Anglemont de Tassigny *et al.*, 2017).

Role of KP in placental invasion, fertilization, and reproductive disorders

Besides the above described functions of KP, it is also abundantly expressed in the placenta, where it plays role in placental invasion and its level in plasma rises dramatically during normal pregnancy. The urinary measurement of KP may offer a non-invasive and simple method of screening for pregnancy and obstetric complications. Increased plasma KP is associated with reduced miscarriage risk, even after adjusting for age, body mass index, gestational age, smoking, and blood pressure.

KP-54 is also a promising approach to effectively and safely trigger oocyte maturation in women undergoing in vitro fertilization (IVF) as a fertility treatment in women with subfertility (d'Anglemont de Tassigny *et al.*, 2017). KP is a potent stimulus of the reproductive axis in patients with idiopathic HH (IHH), which results from defective synthesis, secretion, or action of GnRH, as well as in women with the hypothalamic amenorrhea (HA), which is the one of the most common causes of period loss in women of reproductive age.

Moreover, alterations of the *Kiss1* gene were found in patients with polycystic ovary syndrome (PCOS), which is a highly prevalent heterogeneous disease characterized by ovulatory dysfunction, hyperandrogenism, and metabolic alterations, and the leading cause of anovulatory infertility. Women with PCOS have dysregulated gonadotropin secretion with higher LH pulsatility and perturbed LH-FSH ratios, which likely contributes to the ovarian phenotype and might be indicative of disrupted GnRH secretory activity. Animal models of PCOS mimic some of the above dysfunctions of the reproductive system. It has also been found that in a rat model of PCOS, prenatal exposure to androgens may result in higher KP and NKB levels in the ARC in rodents (Osuka *et al.*, 2017; Paixão *et al.*, 2017), and hypertrophy of KNDy cells in the ARC of sheep, resembles that seen in KP cells of postmenopausal women (Cernea *et al.*, 2015).

Beyond the well-recognized functions at hypothalamic levels, data strongly support direct production and activity of KP in the testis and its involvement in the control of Leydig cells, germ cell progression and sperm functions (reviewed by Chianese *et al.* (2016)). In mice, *Kiss1* and *Kiss1r* genes have been detected in Leydig cells, seminiferous tubules, and spermatids, but KP has not been detected in spermatids, while KISS1R has been found expressed in the acrosomal region of spermatids and mature spermatozoa. It has been suggested that KP might regulate sperm function as similarly to human sperm, KP triggers an increase in intracellular Ca^{2+} in mouse sperm. Moreover, in vitro fertilization rates decreased after sperm were treated with the KISS1R antagonist peptide 234 (Mei *et al.*, 2013; Hsu *et al.*, 2014).

It has also been shown that transgenic male mice with only a 5% level of *Kiss1* transcripts are fertile and give rise to normal-sized litters, however they have smaller testes and lower FSH levels than normal mice (Popa *et al.*, 2013). Based on above findings it has been suggested that KP could regulate mammalian fertilization (see review Bhattacharya and Babwah, 2015).

KP and GnIR/RFRP as potential links between reproductive and metabolic homeostasis

Reproductive function is tightly regulated by nutritional status and undernutrition or obesity can lead to subfertility or infertility (for reviews see: Seminara, 2014; Gawałek and Sliwowska, 2015). Female mice lacking the KP receptor gained more weight compared to control animals, and this weight gain was caused not by increased food consumption, but by an overall decrease in energy and metabolism. Additionally, *Kiss1r* KO females had higher leptin levels, adiposity and impaired glucose tolerance. In contrast, male *Kiss1r* KO mice had normal body weight and glucose regulation (Tolson *et al.*, 2014). There is also a link between GnIR/RFRP and metabolism regulation – icv administration of RFRP-3 stimulated food intake in adult male rats. Evidence has recently been presented supporting a role for KP and GnIH/RFRP as potential links between reproductive and metabolic homeostasis.

Possible clinical applications of KP, NKB, Dyn and GnIH/RFRP in treatment of fertility disorders

Future research is likely to involve investigation of novel KP and GnIH/RFRP analogs and further exploration of the role of NKB, Dyn and other tachykinins in the regulation of the HPG axis (see reviews Bhattacharya and Babwah, 2015; Chianese, *et al.*, 2016; d'Anglemont de Tassigny *et al.*, 2017; Yang and Dhillon, 2016). KP stimulates gonadotrophin secretion less potently when compared with GnRH; however, KP may stimulate gonadotrophins in a more physiological manner when compared with current therapies. Thus, both KP and GnIH/RFRP based strategies may represent potential therapeutic targets in the treatment of fertility disorders and contraception in human and domestic and wild animals.

Sperm-egg interactions

Disappointing results in human trials against hormone targets led to examination of gamete targets. Sperm proteins are attractive vaccine targets as they are highly immunogenic and are often sperm-specific and hence do not affect other biological processes. Proteins have been chosen based on their sperm-specificity, surface expression, involvement in fertility and ability to raise long-lasting antibodies capable of inhibiting fertility.

Sperm proteins

To date, numerous sperm proteins have been investigated for their immunocontraceptive potential driven in part by the knowledge that males and females with autoantibodies against some of these result in infertility (Adoyo and Koyama, 2003; Naz, 2011). Contraceptive vaccines can trigger the immune system to block indispensable step in the process of gamete interaction during fertilization. These include sperm capacitation, sperm-cumulus interaction, sperm-zona binding, the acrosome reaction, zona penetration and gamete fusion. The challenge is to use sperm antigens that are not found in somatic cells. The ideal candidate should be sperm-specific, be accessible on the surface of the spermatozoa, and have a key role in fertilization. Therefore, targets involved in ZP interaction have received most interest. Individually, the proteins have not been 100% effective, and it is recognized that more than one protein is important, therefore multi-antigen vaccines are now being developed. Some targets are detailed below and their general location on spermatozoa shown in Fig. 2. This is not a comprehensive list as many targets have been investigated, but not pursued (reviewed in Garside *et al.*, 2015).

Izumo

Izumo is found on the surface of mouse sperm, and is essential for egg-sperm fusion. Immune-infertile female sera have circulating isoantibodies against Izumo, which suggests that this protein could have a role in contraceptive vaccine development. Female mice immunized against B-cell epitopes have shown infertility.

Fig. 2 Sperm antigen targets and localization on the sperm.

YLP12

YLP12 is a target arising from research into human sperm-ZP interactions, a dodecamer sequence. The peptide sequence is localized on the acrosomal region of human sperm and is involved in recognition and binding to the ZP. Immunization of female mice has shown reversible infertility.

SP10

One of the early sperm specific proteins investigated as a possible contraceptive target was SP10, a human intra-acrosomal protein. Functional studies have shown that SP10 is involved in sperm-oolemma binding, but not sperm-ZP binding during fertilization in the human.

Posterior head 20(PH20)

PH20 is a sperm surface hyaluronidase, found in a wide number of species. In human spermatozoa it is located on the outer surface of the membrane overlying the acrosome, where it enables sperm passage through the cumulus mass to the ZP.

Sperm protein 17(Sp17)

Spermatozoa express Sp17 to mediate the interaction with oocytes after sperm-ZP contact is initiated (Adoyo *et al.*, 1997, McLeskey *et al.*, 1998). This protein was identified on the apical surface of the head of spermatozoa and along the flagellar tails of mature spermatozoa. This makes an interesting target as it is found across the whole spermatozoa. Structurally, the 151 aa of Sp17 construct a three-domain structure composed of the N-terminal, Central, and C-terminal domains (Fig. 3). The highly conserved N-terminal domain matches 45% to the human type II α regulatory subunit (RII α) of protein kinase A (PKA) that is encoded on Exon 2. This domain can bind specifically to a group of A-kinase anchor proteins (AKAP), including AKAP-3 in sperm flagella. The middle heparin-binding domain of Sp17, which is encoded by aa 76–104 (exon 4), represents the less conserved heparin binding domain. The C-terminal Ca²⁺/calmodulin (CaM) binding domain extends over aa 105–151 (exon 5). CaM transmits the Ca²⁺s messenger response in numerous signal transduction pathways (Gaines, 2006). Sp17 has been sequenced and cloned from human, baboon, mice, and rat sperm; and full length and partial Sp17 sequences of different other species have been deposited into the National Center for Biotechnology Information (NCBI) GenBank records.

Fig. 3 (A) Structural and (B) amino acid sequence alignment of human SP17.

Both human and mouse recombinant Sp17 have been synthesised, and immunization of mice with the sequences has shown significant decrease in fertility. Mouse Sp17 is not available to bind antibody on the surface of live, acrosome-intact spermatozoa, but it is presented on the equatorial surface of live, acrosome-reacted spermatozoa (**Fig. 4(B)**). Likewise, both human Sp17 and synthetic peptides derivatives have resulted in the production of both oviductal and serum antibody titers following immunization of female cynomolgous macaques. **Fig. 4(C)** shows how sperm-egg interactions may be disrupted by antibodies raised against a particular target (such as Sp17).

Equatorial segment protein (ESP)

Sperm-specific human ESP (hESP) protein is localized on the equatorial segment of the acrosome. It has been shown to be involved in acrosome biogenesis and is able to cross react with sera from patients (both male and female). Immunization of female mice with N-terminal mouse ESP significantly decreases fertility and litter size.

SLLP1 (also known as SPRASA)

The presence of this non-bacteriolytic, lysozyme-like protein, was discovered in 2003 in the acrosome of human sperm. This was also found in mouse spermatozoa following the acrosome reaction and has a role in sperm-egg binding and fertilization. Further research in the female, confirmed an oocyte specific membrane metalloproteinase, Sperm Acrosomal SLLP1 Binding (SAS1B), that was found to bind SLLP1. SAS1B knockout female mice showed a 34% reduction in fertility, indicating that SAS1B-SLLP1 had been

Fig. 4 Structural component of the mammalian gametes. (A) Gamete components. (B) Acrosome reaction between the two gametes. (C) Fertilization inhibition by anti-SP17 antibody.

identified as a pair of novel sperm-egg binding partners, involving the oolemma and intra-acrosomal compartment during fertilization. SPRASA is found in both sperm and oocytes, so could be used effectively as a male and female vaccine. It is highly conserved in different animal species, including farm animals. Female mice immunised with SPRASA have shown significant decrease in fertility (Wagner *et al.*, 2015).

LDH-C4

This is one of the most studied sperm proteins. In male animals orchitis has been observed, but in female animals there are no side-effects. The protein has been tested in mice, rabbits, baboons, but full infertility has not been achieved.

Zona pellucida

The ZP plays an essential role in the fusion of the oocyte and spermatozoon during mammalian fertilization. The ZP is also involved in the induction of the acrosome reaction, the prevention of polyspermy, and protection of the early embryo. Immunocastration with porcine ZP has been commonly used in pest and zoo species. However, long-term ovarian dysfunction remains an issue (Joonè *et al.*, 2017). Taken together with a lack of understanding for why some species are susceptible to ovarian dysfunction while others are not, this vaccine is not used in humans. However, it may have a continuing role in effective immunocastration in some situations.
